The man who discovers a practical method of dealing with Horse-sickness will be one of the greatest benefactors of this country. There has always been a tradition that a large money reward is awaiting this discovery. I do not know whether this is well founded or not, but certainly such a work would well deserve the highest possible reward. The best reward is to give the successful investigator more opportunity and more assistance in pursuing his beneficent work. The reward given by the French people to Pasteur was the Pasteur Institute; by the German Government to Koch, the Imperial Hygienic Institution.

Catarrhal Fever of Sheep: Blue Tongue.

This disease was first described by Hutcheon, the Chief Veterinary Surgeon of Cape Colony.[1] It is very similar in many respects to Horse-sickness. Both these diseases occur most often in low-lying, damp situations, such as river valleys and the coast plain. They also occur at the same time of the year; that is, from January to April. Blue Tongue, like Horse-sickness, is probably carried from the sick to the healthy by means of some night-feeding insect. At the same time the diseases are not identical, since the inoculation of Horse-sickness blood into a sheep does not give rise to Blue Tongue, nor the blood of the sheep injected into the horse give rise to Horse-sickness.

To Mr. Spreuill, Government Veterinary Surgeon in

[1] It is to Mr. Hutcheon that South Africa owes its knowledge of many stock diseases. For the last twenty-five years he has laboured with the utmost earnestness in Cape Colony, often under trying conditions, and his description of the various diseases formed the basis of all the modern work done on the subject.

Cape Colony, acting under the advice of Hutcheon, is due the credit of proving that a preventive serum could be prepared capable of immunising sheep against this disease. Dr. Theiler informs me he has repeated Mr. Spreuill's experiments, and they hope to introduce this method of inoculation at an early date.

Heart-water of Cattle, Goats, and Sheep.

This disease was also first clearly described by Mr. Hutcheon. It occurs in the Transvaal, Natal, and Cape Colony, and is responsible for much of the yearly loss among the cattle, sheep, and goats.

Like the last disease—Blue Tongue—it resembles Horse-sickness in many ways, and, in fact, has been described by Dr. Edington as being identical with it. Like Horse-sickness, it is a blood disease with an invisible parasite, so that blood injected under the skin of susceptible animals gives rise to the disease. One difference between the parasites of the two diseases is, that whereas that of Horse-sickness is contained in the fluid of the blood, that of Heart-water is probably restricted to the red blood corpuscles. The serum separated from the blood is incapable of giving rise to the disease, and the straw-coloured pericardial fluid, when injected into susceptible animals, fails to give rise to any symptoms of the disease. Horse-sickness blood filtered through a porcelain filter is still infective; the opposite holds good up to the present with Heart-water. Horse-sickness blood can be kept for years without losing its virulence; Heart-water blood loses it in forty-eight hours.

Heart-water has a peculiar distribution, being restricted to the certain tracts of country with a warm, moist climate. It is known to farmers that if they remove their flocks to the high veld the disease dies out.

To Lounsbury is due the credit of explaining these facts. He found that the disease is carried from sick to healthy animals by means of the bont tick, *Amblyomma hebraeum.* This tick leaves its host between each moulting, and a larva which sucks the blood of an infected animal is capable of giving rise to the disease in a susceptible animal either as a nympha or imago. The distribution of this tick corresponds to the distribution of the disease. If this tick could be killed off, the disease would disappear from the country. This could doubtless be done on individual farms by long-continued dipping; but in the meantime some method of immunisation might be devised.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

THE next session at the South-Eastern Agricultural College, Wye, will commence on Monday, October 2, when an address will be given by Prof. Marshall Ward, F.R.S.

THE new session of King's College will be opened on October 3, when an address will be delivered by Prof. Clifford Allbutt, F.R.S., on "Medical Education in London." On October 4 an inaugural lecture will be given by Prof. Arthur Dendy on "The Study of Zoology."

THE inquiry into the general conditions of the home life of the Berlin brass-workers, their education and trade conditions, which the small party of Birmingham delegates carried out last April, is embodied in an interesting and entertaining manner in a report recently issued—"The Brass-workers of Berlin and of Birmingham," by Messrs. R. H. Best, W. J. Davies, and C. Perks (P. S. King and Son, price 1s.). The sensible inferences and criticisms contained in the report are ample evidences of close and accurate observation. The net practical conclusion of the inquiry seems to be that so long as the Birmingham brass-worker confines himself to the reproduction of a number of plain models, his work, especially his polished brass-work, is excellent, both in price and in finish; but "the Berlin training schools have produced a class of artisans with artistic talent, who find ready employment and are of great assistance to the employers. . . . A proper apprenticeship to his trade has fitted him (the Berlin brass-worker) and placed him in a position to supply the internal construction of intricate work without every minute detail being put down for him on paper. In the bronzing and treatment of the finish a greater freedom is apparent and a greater variety and novelty"; in fact, "they lead the way, we follow. . . ." The moral is obvious; indeed, in the further discussion of this point we find what is undoubtedly the most generally applicable and valuable criticism in the whole report:—"It is on the intellectual side that Birmingham requires to adapt itself to changed conditions: not to cheapening its wares but to getting more conception into them."

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, April 13.—"The Amplitude of the Minimum Audible Impulsive Sound." By Dr. P. E. **Shaw.**

In a previous paper (*Phil. Mag.*, December, 1900) the author found this quantity by direct measurement, and Rayleigh, Franke, Toepler, and Boltzmann have investigated the minimum audible for continuous sound. In each of the above researches the micrometer was not sensitive enough actually to measure the least audible amplitude; the relation of current to amplitude was determined for relatively large amplitudes, and separate measurements were made of the current which gives the least audible sound. Extrapolation then gives the amplitude in question.

The present paper shows how the amplitude can be measured directly without extrapolation; it is even possible, as shown in the tables, to measure movements the amplitude of which is too small to be audible. The instrument is the improved electric micrometer described at the Royal Society (see p. 495), which is capable of showing a movement of 0·4 $\mu\mu$.

There are two distinct parts in the determination:—

(1) Observe the position of the diaphragm of a telephone when at rest, by making electric contact; draw away the measuring point of the micrometer and pass a steady current through the telephone so as to move the diaphragm to a new position of rest. Now move up the measuring point to the diaphragm, watching the micrometer screw and listening to the contact. Thus measure the movement of the diaphragm due to a set of steady currents down to such small ones as cause imperceptible motion. Plot the relation between movement and current.

(2) Apply the ear to the telephone and pass through it the same set of currents as before. For each current, except the smallest, a sound is heard when the current is stopped. We thus learn the relation of current to audibility.

The curve above at once gives the relation of amplitude to audibility. The sound is impulsive, for the diaphragm is released from a position of strain, vibrates under great damping, and soon comes to rest.

Both right and left ear of the author were used. He found, averaging results, 0·7 $\mu\mu$ as result for the right ear, and 0·9 $\mu\mu$ for the left.

The fundamental of the diaphragm when clamped hard to the case was found by testing it against tuning forks to have frequency about 580.

The following table of amplitudes is given:—

	A	B
Just audible	0·7 $\mu\mu$	0·14 $\mu\mu$
Just comfortably loud	50 $\mu\mu$	10 $\mu\mu$
Just uncomfortably loud .	1000 $\mu\mu$	200 $\mu\mu$
Just overpowering ...	5000 $\mu\mu$	1000 $\mu\mu$

The word "just" here implies in each case the lower limit. The amplitude of the diaphragm must not be confused with that of the air which it vibrates. Lord Rayleigh obtained the relation between these amplitudes to be roughly 5 to 1.

Column A gives numbers actually found in the telephone, and using Rayleigh's factor we obtain column B for the corresponding amplitude of the air.

It should be observed that 0·14 $\mu\mu$ is the smallest audible amplitude for an expectant ear when the conditions as to silence are exceptionally favourable; yet 10 $\mu\mu$ is the amplitude for the smallest audible sound in air, about which the ear can be quite sure when the conditions are normally favourable, and the ear not listening for the sound.

From the results found the author calculates the ampli-

tudes near the source of various great sounds, *e.g.* thunder, cannon firing, and volcanic explosions. He gives reasons for supposing that in rough terms these are not more than 1/12 mm., 1/4 mm., 1/200 mm. respectively. The volcanic sounds are carried to very great distances; but the sound source is very large in extent, and the amplitude at the source therefore may not be very great.

June 16.—"The Absorption Spectrum and Fluorescence of Mercury Vapour." By W. N. **Hartley**, F.R.S.

The author having undertaken the investigation of the absorption spectra of metals in a state of vapour, the first substance examined was mercury. It was volatilised in a flask of Heraeus's quartz glass, with a side tube to the neck from which the metal may be distilled and condensed. The rays from a condensed spark were passed through the flask and on to a cylindrical condensing lens of quartz which focused the rays on to the slit of a quartz spectrograph.

The Absorption Spectrum.—The whole rays were transmitted from the red to a point in the ultra-violet where there is a tin line at λ 2571·67. From there to λ 2526·8 there is a very sharply defined and intense absorption band, somewhat degraded on the side towards the red, beyond that the rays are transmitted with full intensity to a wavelength about 2000.

The Fluorescence.—When the mercury was boiling briskly the whole side of the flask nearest to the spark was lighted up with a green fluorescence; this penetrated about one-third of the space within the flask, and lighted up the interior. The quartz glass itself was not fluorescent in the slightest degree. Solutions of mercuric chloride showed no absorption band.

The absorption band in the vapour of mercury belongs to the vapour, and is accompanied by strong fluorescence between a certain maximum and minimum of temperature lying very near to the boiling point. It is a question still undecided whether the rays absorbed by mercury vapour, as shown by the band measured, reappear with a lowered refrangibility as yellowish-green light in accordance with the law of Stokes.

NEW SOUTH WALES.

Royal Society, June 7.—Mr. H. A. Lenehan, president, in the chair.—On the so-called gold-coated teeth in sheep: Prof. A. **Liversidge.** Paragraphs in some of the London and Sydney newspapers have stated that gold-coated teeth have been found in Australian sheep. The author recently received the lower half of a sheep's jawbone from Dubbo, the teeth of which are more or less completely incrusted with a yellow metallic substance, but more like iron pyrites (marcassite) or brass than gold. The deposit is about 1/32 of an inch, or less than 1 mm. in thickness. Under a half-inch objective it is seen to be made up of thin translucent layers, but there is no recognisable organic structure. The metallic lustre is due to the way in which the light is reflected from the surface of the superimposed films. The scale partly dissolves in dilute acids. The residue consists of filmy organic matter, still possessing a metallic sheen, although white in colour instead of yellow. The chemical examination shows that the incrustation on the teeth is merely a tartar-like deposit, made up principally of calcium phosphate and organic matter.

July 1.—Mr. H. A. Lenehan, president, in the chair.—Observations on the illustrations of the Banks and Solander plants: J. H. **Maiden.**

PARIS.

Academy of Sciences, September 4.—M. Troost in the chair.—Researches on the insoluble alkaline substances formed by humic substances of organic origin, and their *rôle* in plant physiology and in agriculture: M. **Berthelot.** The experiments were made with fresh and old specimens of humic acid prepared from sugar, with dead leaves, and with soil. The substances extracted by maceration with water and by distillation with water in presence of potassium and calcium salts were analysed.—The eclipse of the sun of August 30 observed at Paris: M. **Lœwy.** In spite of the interference caused by cloud, the partial eclipse was observed at Paris under good conditions. The times of first and second contacts were obtained, and numerous photographs were taken.—Actinometric measurements carried out during the eclipse of August 30: J. **Violle.** The observations at Trappes, Bordeaux, and on the Pic du Midi were spoilt by the weather, but satisfactory results, details of which will be communicated later, were obtained at Bagnères and Sfax.—On the existence in certain gooseberry trees of a compound furnishing hydrocyanic acid: L. **Guignard.** In the case of the common red gooseberry, hydrocyanic acid has been obtained from the leaves at all stages of their growth, but is absent from the fruit. The leaves of several other species have been examined for prussic acid with negative results.—On the glycuronic acid of the blood: R. **Lépine** and M. **Boulud.**—The secretary read telegrams from various observers relating to the solar eclipse of August 30, from which it would appear that satisfactory observations were obtained at Alcasebre, Sfax, Guelma, and Philippeville, clouds interfering at Cistierna, Burgos, Tortosa, and Alcalá de Chisbert.—Observation of the eclipse of August 30 at Alcalá de Chisbert (Spain): Marcel **Moye.** The brilliant corona was the most marked feature of the eclipse.—On the same: R. **Mailhat.** Remarks on some photographs taken at Paris.—On the envelopes of spheres of which the two sheets correspond with conservation of the angles: A. **Demoulin.**—On the importance of the effect of irradiation in spectrophotography: Adrien **Guébhard.**—The constitution of the copper aluminium alloys: Léon **Guillet.**—On the origin of lactose. The effects of injection of glucose into females during lactation: Ch. **Porcher.**—The geology of the southern Carpathians: G. M. **Murgoci.**—The influence of the solar eclipse of August 30 on the earth's magnetic field at Paris: Th. **Moureaux.** The oscillations observed during the eclipse were much greater than the regular diurnal variations.—On the polarisation of the sky during the eclipse of the sun: M. **Piltschikoff.**

THURSDAY, SEPTEMBER 21, 1905.

THE EVOLUTION OF MATTER.

L'Evolution de La Matière. By Dr. Gustave Le Bon. Pp. 389. (Paris: Flammarion, 1905.) Price 3.50 francs.

DR. GUSTAVE LE BON has written many books. Some twenty volumes, besides papers in current scientific periodical literature, have issued from his pen. History, travels, tobacco-smoke, anthropology, horsemanship, and psychology have in turn attracted his sympathetic interest.

The work before us sets forth Dr. Le Bon's theories of matter and energy, and contains, in a small-print appendix, an abstract of the experimental evidence on which he is content to rest those theories.

According to the author, matter itself is merely a form of energy—probably vortex energy in the luminiferous æther. Matter disintegrates—spontaneously in radio-active substances, but also under the influence of certain agencies such as heat or chemical action, which are compared with the spark that fires a barrel of gunpowder. After giving rise to "les produits de la dématérialisation de la matière: ions, électrons, rayons cathodiques, &c.," all things finally pass into "l'élément immatériel de l'univers: l'Éther." By the dissociation of matter, energy is transformed, and "c'est de l'énergie intra-atomique libérée par la dématérialisation de la matière que dérivent la plupart des forces de l'univers."

The chief experimental evidence on which Dr. Le Bon relies may be grouped under two heads:—(1) the emission of negatively electrified particles by metals when incandescent and when subjected to the action of ultra-violet light; (2) the slight radio-activity which may be detected in ordinary materials.

The emission of negative corpuscles from metals under the influence of heat and light undoubtedly occurs, though it is not to the author's speculative opinions that we owe the experimental demonstration of the fact. As a speculative hypothesis, the idea that the corpuscles are emitted during the disintegration of the atoms of the metal is perhaps worth bearing in mind. But, on a review of the evidence known at present, it seems unlikely that the removal of these slow-moving negative corpuscles results in the instability of the atom from which they are derived. There is no evidence that an electric discharge through a gas produces new elements, while the ions of liquids and gases, which result from the removal of the corpuscle, again yield the original atom when neutralised. Such processes are to be distinguished sharply from the irreversible changes which occur in true radio-activity, when bodies of atomic mass (α rays) or fast-moving corpuscles (β rays) are projected. In this case, new chemical substances always appear, and the process seems to be unaffected by heat, light, or any other physical or chemical agency. This essential distinction is not noticed by Dr. Le Bon, who assumes that the production of a corpuscle is itself a proof of atomic disintegration.

The author claims that he was the first to show that radio-activity is a universal phenomenon, not confined to a few substances:—

"Mon premier mémoire sur la radio-activité de tous les corps sous l'action de la lumière a paru dans la *Revue Scientifique* de mai 1897. Celui sur la radio-activité par les actions chimiques a été publié en avril 1900. Celui montrant la radio-activité spontanée des corps ordinaires a paru—toujours dans la même revue—en novembre 1902. Les premières expériences par lesquelles les physiciens aient cherché à prouver que la radio-activité pouvait s'observer avec des corps autres que l'uranium, le thorium et le radium n'ont été publiées par Strutt, McLennan, Burton, &c., que de juin à août 1903."

We may first notice that Dr. Le Bon classes the effects of light under the head of radio-activity. This, it may be argued, is a matter of definition, and the author is at liberty to give a meaning to the word radio-activity different from that adopted by all other physicists. But it is well to point out that many experiments on the electric effects of the incidence of light on metals had been made before the year 1897, notably by Elster and Geitel between 1889 and 1895. Dr. Le Bon may have been the first to suggest that the effects were due to the emission of particles, but no conclusive evidence was obtained until the experiments of J. J. Thomson and Lenard, in 1899, had determined the ratio of the charge to the mass, and identified the particles with those found in kathode rays.

Secondly, doubt has been thrown on the emission of rays by substances undergoing chemical action by the recent experiments of Mr. N. R. Campbell, who has traced some, at all events, of the effects to secondary causes connected with the heat of reaction. Here Dr. Le Bon does not seem always to separate clearly the ionisation which may be produced in a gas by contact with substances undergoing chemical change, and the emission of radiations, more or less penetrating, characteristic of true radio-activity.

Thirdly, in examining the spontaneous radio-activity of ordinary materials, the author seems to underestimate the effect of the minute traces of radium which are now known to be distributed widely. He claims Prof. J. J. Thomson's experiments on the emanations emitted by various natural substances and underground waters as a confirmation of his view that all matter is radio-active. Now, Thomson found that the rate of decay and the phenomena of excited activity in those emanations which he examined closely were about the same as those of the radium emanation, and his experiments should be regarded as an indication of the prevalence of radium rather than of the radio-activity of ordinary materials. It is true that further experiments by Thomson, Cooke, Campbell, Wood, and others have now made it probable that ordinary metals, at all events, are slightly radio-active. But, to eliminate the effects of strongly radio-active impurities, it is necessary to take the utmost precautions, both in the experiments themselves and still more in the interpretation of the results. There seems little evidence that, in either respect, Dr. Le Bon recognised the necessity of such precautions.

It will be gathered that the author takes a point of view which is not that of the majority of physicists who have investigated these subjects. Revolutionary opinions may prove a valuable tonic to the orthodox in physics as in other matters. It is not because he is heterodox that we are not satisfied by Dr. Le Bon's book. It is because he seems to us to fail in grasp of the subject, to confuse phenomena which are essentially different, and to be blind to evidence which does not support his hypotheses.

A belief in the evolution of matter is fast becoming not only possible but inevitable. Dr. Le Bon has written readable speculations about that evolution, and here and there has thrown out an interesting idea; but the evidence on which that belief must be founded is not that put forward by him. His book calls to mind the advice offered by a famous Lord Chief Justice to a brother judge, that it was sometimes safer to give one's conclusions without the reasons which had led to them.

W. C. D. W.

THE FÆRÖES AND ICELAND.

The Faeröes and Iceland; Studies in Island Life. By N. Annandale. With an appendix on the Celtic Pony by F. H. Marshall. Pp. vi+238; illustrated. (Oxford: Clarendon Press, 1905.) Price 4*s*. 6*d*. net.

THE name of Mr. Nelson Annandale has been of late years so intimately associated with the Malay Peninsula and its zoology and ethnology that it comes somewhat as a surprise to find it on the title-page of a work dealing with such totally different surroundings as those of the Færöes and Iceland. It appears, however, that between the years 1896 and 1903 the author spent several summer holidays in these remote islands, and contributed a series of articles on his experiences to *Blackwood's Magazine* and the *Scotsman*, and that it is these delightful articles, in a more expanded and elaborated form, with the omission of certain purely technical details, which form the basis of the work before us.

As Mr. Annandale suggests in his opening chapter, most persons probably regard the Færöes as little more than mere Arctic rocks, teeming with sea-birds, in the ocean; and they will accordingly be surprised to learn that, as a matter of fact, although lying nearly a couple of hundred miles to the north-west of Shetland, they enjoy a climate warmer than that of many parts of Scotland, while their vegetation, if rarely more than a few inches high, is as luxuriant as the shallowness of the soil and the winter storms will allow. The buttercups, too, seem larger, and the bushes of a brighter green, than on the mainland. These islands have also to be regarded as desirable spots, for it appears that although a few years ago they possessed a couple of dozen policemen, the *moral* of the population has been so excellent that the services of these guardians of the peace were found no longer necessary, and the force has consequently been disbanded. A truly remarkable record!

The first two chapters deal with the people of the Færöes and their mode of life, and will be found to contain a number of interesting observations on their ethnography and the implements of the islanders. The invasion of Iceland by the Moors in the seventeenth century forms the subject of a third chapter, but perhaps the most interesting part of the whole book is that dealing with the wonderful bird-cliffs of the Westman Islands, and the clever manner in which the natives capture puffins and other birds in nets. The fulmar appears, indeed, to be very valuable to the Westmaners, supplying them with both food and light. Other chapters deal with Iceland and its products, and the insects and domesticated animals of both that island and the Færöes.

Mr. Annandale deserves, indeed, our most hearty congratulations, and has succeeded in producing a most admirable little work which may be perused with interest alike by the general reader and by those who have enjoyed, or expect to enjoy, the opportunity of visiting the islands he so happily describes. Whether similar congratulations should be extended to Dr. Marshall for his share of the work we are not fully assured. That gentleman seems, indeed, to be under the impression that no one save Profs. Ewart and Ridgeway has written in this country on the origin of the horse. Otherwise he would have scarcely credited the former with being the first to regard Przewalsky's horse as a variety of *Equus caballus*. Neither would he have omitted to notice that an earlier name than *przewalskyi* has been suggested as referable to this animal, and also that Prof. Ewart's *E. celticus* is probably inseparable from the earlier *E. hibernicus*. Moreover, he might have pointed out that it is difficult to understand how Prof. Ridgeway's new name of *E. c. libicus* can stand for the barb, when the Arab horse has long since received a technical name of its own.

R. L.

OUR BOOK SHELF.

Le Système des Poids, Mesures et Monnaies des Israélites d'après la Bible. By B. P. Moors. Pp. 62+1 plate of figures and 6 tables. (Paris: A. Hermann, 1904.)

THE first part of this work consists of an inquiry respecting the numerical value adopted by the Israelites at the time of Solomon for the constant π, the ratio of the circumference of a circle to its diameter. M. Moors obtains the greater part of his material for this investigation from the dimensions of the "molten sea" in Solomon's temple, as stated in I. Kings, vii., 23–26, and II. Chronicles, iv., 2–5. These dimensions have led some writers—notably Spinoza and Hoefer—to the opinion that the Israelites knew of no nearer approximation to π than the whole number 3. The specification of the molten sea is not, however, sufficiently complete to determine its shape with any degree of certainty. Some commentators have considered it as cylindrical, others have followed Josephus in ascribing to it a hemispherical form, whilst Zuckermann suggests a combination of cylinder and parallelepiped. The author of this work, who is firmly of opinion that the Israelites accepted a value for π very close to 3·142, has found it necessary in support of his argument to assume that the molten

sea had the form of a lipped cylinder. Adopting the description given in I. Kings, which differs somewhat from that of II. Chronicles, M. Moors has deduced for the cubic contents of the *bath*, a measure of capacity frequently met with in the Old Testament, the relation

$$1 \text{ bath} = \tfrac{1}{8} \text{ (Mosaic cubit)}^3.$$

The remainder of the work deals with the system of weights, measures, and coinage in use among the Israelites. Carefully disclaiming any bias in questions theological, he adopts the Bible as the chief authority on the subject of which he treats. The weights and measures mentioned in the Bible are not, however, always very clearly defined, and in attempting to combine them in a homogeneous system we are confronted with apparently hopeless inconsistencies. Owing to this difficulty M. Moors finds it necessary to have recourse to materials of somewhat incongruous character. From a strange medley of midwives, manna and mummies, he evolves, with much ingenuity, a series of metric equivalents for the weights and measures of the Israelites. He claims that his equivalents are confirmed by all those passages in the Bible which contain references to weights and measures. It is interesting to note that his value for the length of the cubit, viz. 443·61 millimetres, agrees very closely with the value obtained recently by Sir Charles Warren (17·64 inches, = 448·05 mm.).

It is hardly possible to accept the view of M. Moors that the Bible was intended *inter alia* as a text-book on mensuration. In spite of his laudable effort to throw light on the old Hebrew weights and measures they still remain dim to us. In the region of metrology the Israelites would indeed appear to have baffled the commentator, and to have buried their authoritative standards "deeper than did ever plummet sound" out of the excavator's reach.

So far as we have checked the numerical calculations made by M. Moors, we have found them invariably accurate. There is, however, an obvious misprint in the last line of his letterpress; "43·5" should read "43,500."

A Primer on Explosives. By Major A. Cooper-Key. Edited by Captain J. H. Thompson. Pp. xii+94. (London: Macmillan and Co., Ltd., 1905.) Price 1s.

THIS little book should prove of great value to those for whose benefit it has been mainly written, viz. the local inspectors under the Explosives Act, and those dealers whose trading necessitates the handling and storage of explosives.

No one can better realise the want of some little handbook on the subject than H.M. Inspectors, and it is to meet this want that Major Cooper-Key has written this useful book, which, it is pointed out, is "not a treatise on explosives." The author gives a short description of the manufacture of the chief explosives, but its great value will be found in the sections devoted to special risks with each class, the methods of packing and storing, and a particularly useful chapter on the general construction and management of a store, the destruction of explosives, &c.

It is certain that a careful study of the book by local inspectors will lead to a better understanding of the whole question of explosives and the Act generally, and hence to a more intelligent performance of their responsible duties. For those traders and users who have the handling of these goods after they have left the manufactory the book should be equally valuable, and it should do much to lessen the risk of those untoward accidents which occur from time to time, generally from ignorance of the properties of the bodies dealt with. J. S. S. B.

A Note-book of Experimental Mathematics. By C. Godfrey and G. M. Bell. Pp. 64. (London: Edward Arnold, 1905.) Price 2s.

THIS book gives concise instructions for carrying out a number of simple quantitative experiments in mechanics. It is specially suited for students who intend to sit for Army Entrance Examinations, but the excellence of the course outlined renders the book very serviceable for general use in schools; the students get accustomed to fundamental methods of measurement, obtain concrete conceptions of elementary science, and secure much data well adapted to serve as examples and illustrations in a course of practical mathematics. The experiments include measurements of lengths, areas, volumes, weights, specific gravities, fluid pressures, forces, moments, velocities, accelerations, and many other physical quantities. A full and careful list is given of the requisite apparatus and fittings, and the book will be of very great assistance to teachers in the arrangement of a thoroughly sound elementary course of experimental science.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Cause and Prevention of Dust from Automobiles.

THE article on the above subject in the issue of NATURE for September 14 (p. 485) is an important contribution to a subject of great interest and importance to the community, but it contains a statement with reference to tar-macadam which in the interests of engineers should, I think, be verified. Speaking of "Tarmac" the writer says, "the slag is thoroughly impregnated, so that if the pieces are broken further a tarred surface is still found."

I have examined many specimens of tar-macadam, including "Tarmac." I have never found any sign of penetration of tar. I am aware that some believe in this alleged penetration, but it seems to be obvious that any material sufficiently porous to enable tar to saturate it would be totally unfit for road-making.

That tar-macadam, and, of course, "Tarmac," have virtues for motor road-making may be admitted; but this penetration theory is not the reason, and it is a pity that the myth should still exist, as it tends to prevent the trial of other substances far more suitable for roads than furnace slag.

The reason why tarred granites and similar hard stones have not hitherto been found so effective is entirely a matter of surface adhesion. Given a suitable tar mixture, there is no reason why hard, non-porous stone should not be as efficient as slag. Penetration has nothing to do with it. J. VINCENT ELSDEN.

38 St. Stephen's Gardens, Twickenham.

IN reply to Mr. Elsden, I agree that it is of no use to hold mythical views. I think, however, that he is really mistaken in his views that the slag in "Tarmac" is not penetrated by the tar. Possibly it may not be penetrated by the most viscous constituents, but upon examining a broken piece of "Tarmac" I have found that the surface is distinctly darker than that of slag which has not been treated. The difference is very noticeable under the microscope, and if a bit of slag from the interior of a treated portion is heated the tar is readily seen, which fact appears to be conclusive evidence that penetration by the tar takes place. I do not, however, suppose that the penetration is very uniform, as slag is not a very uniform material, and therefore in some parts the effect might not be so evident. W. R. COOPER.

82 Victoria Street, S.W.

THE SOLAR PHYSICS OBSERVATORY ECLIPSE EXPEDITION.

Innsbruck, September 12.

SINCE my last letter, which was dated August 26, I have had so little time for writing that I take the first opportunity to record the events that followed the last communication. Passing over August 28 and 29, which were spent in giving the final touches to the various instruments, putting in the eclipse mirrors, and in rehearsing, we come to the eclipse day itself. Turning out at 5 a.m. and scanning the sky, a glance showed that clear weather conditions for eclipse time were very doubtful. Heavy black clouds were sailing majestically across the zenith, and still blacker ones were slowly moving nearer the horizon. There were, however, small breaks here and there where blue patches were exposed for brief intervals, but it seemed that the chances for a clear eclipse were very small.

FIG. 1.—The officers of H.M.S. *Venus* volunteering for eclipse work on the quarter-deck.

It was not long, however, before many of us reached our camp. Rain had fallen about 4 a.m., and at about 6 a.m. another shower helped still further to lay the dust, which had proved such a menace to the smooth working of the clocks. The previous evening all dark slides had been carefully filled and noted with their particular make of plates, and these now were distributed to the different workers.

Fortunately we were working in an area enclosed by a wall, so that only those who had received special permission could enter. Needless to say, invitations were numerous, and included the majority of those who had helped us in various directions during our preparations.

At the time of first contact, clouds near the region of the sun were very few, and we observed this under excellent conditions. As time progressed, a great bank of clouds was seen gradually working its way along from the west, and it became a race between the clouds and the moment of second contact, *i.e.* the beginning of totality. The diminishing crescent became smaller and smaller at about the same rate as the clouds over the sun became thicker and thicker. The clouds won! The moment of second contact could not be observed! We went, however, through our programmes, knowing that we were photographing nothing. Venus became a brilliant object in the west seen through a break.

6-inch prismatic camera. 16-feet coronagraph tent. The tent of Lieut. Horne (Commandant of Camp) and myself.

FIG. 2.—Visitors being shown round the camp on the day before the eclipse. Looking west.

Fortunately there were two currents of air at work in the upper regions, one coming from the south and the other from the west. This intermingling of currents was possibly the cause of the thinning of the clouds over the sun, and gave us a view of the corona for brief intervals through, as it were, a thin

veil; the clearest intervals were towards the end of totality. The burst of sunlight from the north-west limb of the sun heralded the end of totality, and thus ended the work of the instruments and the greater majority of the different parties.

We were all, however, bitterly disappointed. So much trouble had been taken to make everything work with the maximum of efficiency, but, alas! with so small a result. Prismatic cameras of high dispersive power and prismatic reflectors of long focal length, to say nothing of long-focus lenses for three-colour negatives, are not conducive to good results in a cloudy sky!

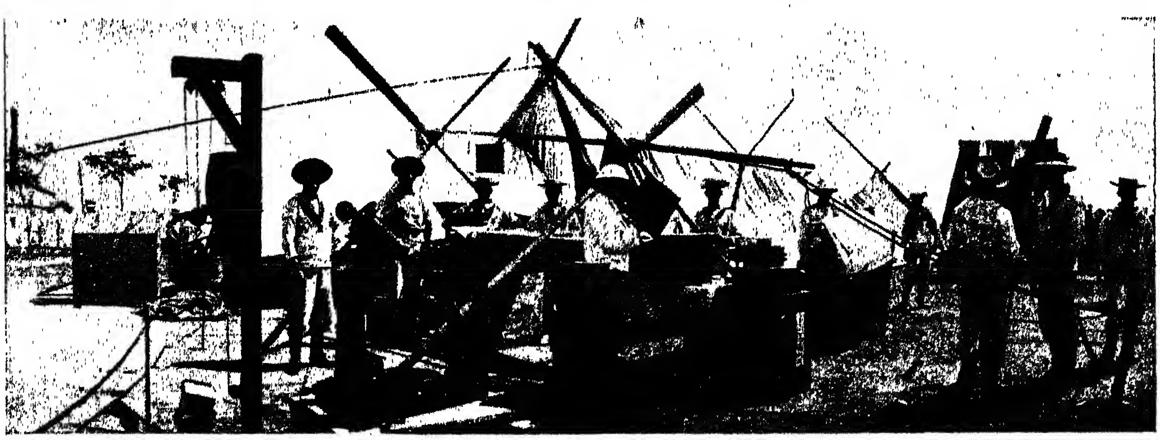
During the few moments that were available between the exposures of the different plates in my instrument I saw enough of the corona to know what a magnificent sight it would have been had it been seen in a cloudless sky. The enormously brilliant red prominence in the north-east quadrant was an undoubted feature of this eclipse, and nothing like it was seen by me in either the 1898 or 1900 eclipses. From several accounts the landscape was illuminated by this red radiating object, and sunset effects were recorded by other observers.

The corona itself was of the maximum type, streamers radiating in all directions even very near the poles. At the north pole there was a region displaying the beautiful rifts seen at best during eclipses at a minimum stage, but at the southern pole no such distinctive structure was seen. Unfortunately the eastern and western limb of the sun were shrouded in thicker haze than the north and south region at the time that I had my longest glance. It was therefore about the solar poles that the longest streamers were seen by me, and two in the south-east quadrant extended for at least two solar diameters.

Mr. F. McClean. De la Rue coronagraph behind the men. Grating spectrograph. Mr. Howard Payn.

Fig. 3.—Taken after the beginning of first contact. The tents over the instruments have all been removed. The 16-feet coronagraph, with Mr. F. McClean and his naval staff.

The eclipse being over there was then nothing more to do than to collect all the photographic plates exposed and commence with the packing up of the instruments. It is one thing to set up the instruments and another to take them down. By the evening of the same day about 50 per cent. of the packing up had been completed.



Siderostat. Tube of 6-inch prismatic camera. Packing cases supporting small cameras with gratings. Cusp telescope. Three-colour camera in distance.

Fig. 4.—The 6-inch prismatic camera, showing staff and positions for the small grating cameras and the cusp telescope.

In the cool (?) of the evening the development of the plates was commenced. Those which promised to have some kind of record on them were taken first. To sum up the results, now that the whole set has been developed, it may be said that we have been far more fortunate than was at first anticipated. The prismatic reflector worked by Mr. Butler succeeded in securing an excellent picture of the lower corona, the solar diameter being about 8½ inches. The 16-feet

coronagraph operated by Mr. F. McClean obtained a fine photograph of the corona with excessively sharp detail and good extension. The De la Rue coronagraph in charge of Lieut. Trench, R.N., was fortunate enough to secure three negatives, all of which will be very serviceable, as the focus was so well adjusted. Unfortunately the long exposures required for the three-colour camera operated by Lady Lockyer could not be secured in consequence of clouds. The $3\frac{1}{2}$-inch Newton, mounted equatorially and worked by Staff-Surgeon Clift, obtained two successful exposures. The instrument in my charge secured four negatives that will prove useful, one of which displays the green coronal ring clearer than those which were secured in the 1898 or 1900 eclipses, and several other distinct coronal rings in addition. The spectrum of the lower chromosphere at the beginning or end of totality was not obtained. The objective grating spectroscope worked by Mr. Howard Payn produced one out of two exposures made, and shows the spectrum of the larger prominences and the green coronal ring.

The observers of the shadow bands gained a great amount of information as regards their size, rate of motion, and direction. The coronal sketchers obtained very concordant results, and the other parties gleaned much useful information, which will be published later, as the observations have not yet been brought together.

FIG. 5.—The camp four hours after the eclipse, showing how quickly the instruments were removed.

By the evening of Sunday, September 3, the whole of the instruments, tents, dark room, and smaller huts were comfortably on board, and we steamed away to Palermo, leaving our camp as bare as we found it. Two copies of each negative had been made and separately packed to ensure loss against accident.

With the exception of Mr. Butler, who proceeded to Malta in H.M.S. *Venus*, and of Mr. Payn, who remained at Palma, our party bade farewell to the officers and men of H.M.S. *Venus* who had worked so hard, and whom Dame Nature had treated so badly. Crossing to Naples, where we left Mr. F. McClean, we took the train the same morning to Rome, and after a short rest and a little sight-seeing journeyed to Innsbruck, travelling through the beautiful Brenner Pass, to attend the meeting of the Solar Commission of the International Meteorological Committee. Perhaps by the time that the next eclipse occurs we may know a little more about "weather" to enable observers to go to regions where they will not be totally or even partially clouded out!

WILLIAM J. S. LOCKYER.

INTERNATIONAL METEOROLOGICAL CONFERENCE AT INNSBRUCK.

THIS International Meteorological Conference was opened at Innsbruck on September 9, when Dr. Hildebrandsson, the secretary of the International Meteorological Committee, read the report of the operations of that body on the part of M. Mascart (president) and himself, and explained that at the Southport meeting in September, 1903, Dr. Pernter's proposal that a conference of the directors of meteorological services should be held at Innsbruck this year, similar in character to those at Munich in 1891 and Paris in 1896, was favourably regarded and subsequently adopted.

The vacancies which have occurred on the committee from various causes have been filled by the appointment of Dr. Palazzo and Dr. Shaw in succession to Prof. Tacchini and Dr. Scott. Dr. Hildebrandsson was elected secretary on the retirement of Dr. Scott, who, since the creation of the committee, had performed this function with a zeal and devotion which would be most gratefully remembered. The following changes have also been made:—M. Chaves, director of the Meteorological Service of the Azores, was appointed in place of Admiral de Brito-Capello, Dr. Hellmann in succession to Prof. von Bezold, and M. Lancaster in succession to M. Snellen.

Sir John Eliot, having ceased to be director of the Indian Meteorological Service, tendered his resignation as a member of the committee, but, with the approval of the India Office, communicated through Dr. Shaw, the committee invited him to retain his seat, as representing in Europe the Meteorological Service of India. Thus the committee has the great advantage of counting among its members residing in Europe a man of experience and possessing a thorough knowledge of the meteorology of the tropics.

According to the report presented by M. Wild and Dr. Scott to the conference at Munich, and adopted

by it, the principal object of these private conferences of the directors of meteorological services was "the discussion of concrete questions, the arrangements of procedure as to methods of observation and calculation, and the organisation of common investigations." Since that period several investigations have been organised by the subcommittees nominated by the international committee.

The Munich conference nominated a committee for cloud observations, under the presidency of Dr. Hildebrandsson, whose duty it was to publish an international cloud atlas, and to organise and direct observations and measurements of clouds in different countries during a year. The cloud atlas was published in 1896 by MM. Hildebrandsson, Riggenbach, and Teisserenc de Bort. International cloud observations and measurements were made at a great number of stations from May 1, 1896, to the end of 1897, on a plan fixed by the committee at the meeting at Upsala in 1894. The publications, in accordance with instructions laid down by the subcommittee, have appeared, and the principal results have been published by Dr. Hildebrandsson in a report of which the first part was presented to the international committee at the Southport meeting, and the second part is now presented to the conference. The subcommittee has now completed its work.

At the Paris meeting, in 1896, other subcommittees of a similar character were nominated, *e.g.* an aëronautical committee, with Dr. Hergesell as president, for the purpose of organising international scientific aëronautical experiments, especially simultaneous balloon ascents at different stations. A committee was formed under the presidency of Sir Arthur Rücker for the purpose of international researches on terrestrial magnetism and atmospheric electricity.

These subcommittees have had several meetings, and have organised some important investigations. A third subcommittee was constituted at Paris in 1896 for the study of solar radiation. There have been no special meetings, but M. Violle has presented to each sitting of the international committee a report of the principal researches undertaken in different countries. At the St. Petersburg meeting, in 1899, the international committee appointed a telegraphic subcommittee, under the presidency of Dr. Pernter, with the view of suggesting possible improvements in telegrams for weather prediction. Lastly, at the request of Sir Norman Lockyer and Dr. Shaw, the committee appointed a subcommittee for the study of questions relating to simultaneous solar and terrestrial changes, under the presidency of Sir Norman Lockyer.

The reports of these subcommittees show that their labours have been of the greatest utility for the development of meteorological science. By this means it has been possible to organise and carry out successfully investigations which would have been otherwise impracticable. It is very desirable that all persons occupied with the same or analogous problems should meet periodically, in order to fix ideas and coordinate individual efforts, without in any way restricting personal initiative. It may be asserted with satisfaction, added Dr. Hildebrandsson, that the meteorological conferences organised more than thirty years ago have materially contributed to the development of the science, to uniformity of views, and to agreement between the services of different countries. The constitution of the international committee contributes effectively to the maintenance of good relations, and promotes continuity in the labours of the conferences.

Dr. J. Hann was elected honorary president, and Dr. J. M. Pernter president, of the conference. In the course of an address Dr. Hann said:—

As I am not the official president, I shall take advantage of my privilege of passing over in silence most of the questions which form the programme of the present conference, and I shall devote my attention to certain problems of modern meteorology in which I have a special interest, and the solution of which your discussions will assist.

The use of balloons and kites has brought the exploration of the upper regions of the atmosphere to a degree of development of which we had no idea at the time of the first international congresses at Leipzig and Vienna. Even in 1879 the condition of the question had not changed, when at the congress at Rome I was charged with elaborating plans for observations in balloons and on mountains. We had not then the apparatus for raising kites, and had no idea of the important part they were to play in meteorological science. It was reserved for Messrs. Rotch and Clayton, of Blue Hill, to obtain the excellent results with which we are all acquainted.

Further, unmanned balloons were not invented, which since, thanks to M. Teisserenc de Bort, have furnished such surprising data relating to the temperature of the upper regions of the atmosphere. The exploration of the air by means of manned balloons was carried on without any regular plan, and the observations obtained, as we found out later on, were unsuitable for scientific investigations. It was only more recently, after the older experiments by Welsh had been overlooked and forgotten, that Dr. Assmann produced his aspiration-thermometer, which is capable of giving accurate temperature observations during balloon ascents.

Thus I was only able to recommend observations in captive balloons. I directed attention to the superiority of such observations over those made on mountain summits, which were subject to the disturbing influence of the ground, and gave a daily range of temperature quite different from that observed in free air.

But as observations in captive balloons were limited in several respects, I also recommended that observations should be made on mountains. Mountain observations, although subject to local influences, are of great use; they give us information that observations made in balloons or by means of kites cannot do, viz. the continuous registration of meteorological elements (especially barometric pressure) at a definite altitude, and are indispensable in determining the conditions of the weather in the higher regions of the atmosphere.

I now come to another domain of research, which at the present time has attained increased importance, viz. the problem of weather periods and their connection and dependance on the activity of the sun. This is one of the grandest and most beautiful problems of modern meteorology, for the solution of which astronomers, physicists, and meteorologists must give mutual assistance. One of the services which meteorologists can render in furthering this important object is to obtain suitable observations, by means of which the cyclical variations in the atmosphere and their relations to solar activity may be unequivocally determined.

These observations must fulfil two principal conditions; they must be distributed as uniformly as possible over the globe in order to give sufficient data relating to the conditions of the atmosphere at fixed moments, and must be suitable for closely following the variations in time of these conditions during short as well as in very long periods. The meteorological observations at fixed points must give continuous and homogeneous series of mean and extreme values.

Unfortunately, the older observations do not always satisfy these conditions. It often happened that the principal meteorological observatories, while constantly endeavouring to obtain more exact data, omitted at the same time to take steps for obtaining comparisons between the old and the new series of observations. This remark applies above all to certain barometrical observations. Thermometrical observations subject to local influences, as well as barometrical observations affected by large or unknown instrumental errors, may afford valuable means for determining the variations of meteorological elements, provided that the local influences and the corrections are

constant. These are even more valuable than absolutely accurate observations that are not homogeneous, because the constant errors do not affect the variations. Accordingly I have for many years urged in the *Meteorologische Zeitschrift* that we should endeavour to continue the homogeneous series of means and extremes of the meteorological elements for as many years as possible, and should collect and critically discuss the older series of observations.

Considered from this point of view, the continuation of meteorological observations on mountains is of special value and most urgently to be recommended. They give us information about the condition of the atmosphere in the higher regions which are less exposed to local influences.

Among the results of recent researches, no other has made so great an impression on me as the observations of the British Antarctic Expedition on the retrograde motion of the glaciers now going on in those regions. The renowned great ice-barrier of James Ross has receded thirty miles; the glaciers of Victoria Land are in full retreat, and no longer reach the sea; while, on the other hand, the Arctic glaciers are receding, and travellers report the same thing about the glaciers of the snow-covered mountains of Ecuador and East Africa.

Comparing these facts with reports and observations of the progressive desiccation of Africa and Central Asia, we are confronted with one of the greatest problems of terrestrial physics. This appears the more difficult of solution since we have similar phenomena on a smaller scale which we can closely observe, both as regards geographical and time distribution, but are unable to explain from a meteorological point of view. I refer to the continual retrograde motion of the glaciers of the Alps, which you have the opportunity of seeing in the vicinity of the place of our present meeting. Although this phenomenon is proceeding in a district where one may suppose sufficient meteorological observations, both as to time and geographical distribution, are available, we are still unable to determine with certainty a direct connection between the variations or periods of the meteorological elements and the movements of the glaciers.

Great results are not attained suddenly, but only after long and carefully prepared efforts. You have met here, gentlemen, to deliberate upon the means by which we may solve, step by step, the most important meteorological problems of the present day.

Dr. Pernter proposed that a certain number of questions should be referred to special subcommittees which would present reports, with the view of simplifying discussions at the general meetings. Subcommittees were nominated for the consideration of (1) an international code and comparison of the standard barometers of different countries; (2) new edition of the cloud atlas, and the classification of clouds; (3) reduction of the barometer to sea-level, and questions relating to weather-telegraphy; (4) international study of squalls.

A vote of thanks was accorded to Dr. Hildebrandsson for his services as secretary to the International Meteorological Committee, and a telegram was dispatched to M. Mascart, president of the committee, expressing regret at his absence owing to ill-health.

An account of the subsequent meetings of the committee will appear in another issue of NATURE.

SCIENCE TEACHING IN ELEMENTARY SCHOOLS.

THE issue by the Board of Education of the Blue-book[1] that lies before us is a promising sign. Intended as a supplement to the necessarily somewhat rigid and mechanical "Code," it indicates the progress which rational ideas upon elementary education have made in the national councils since the days when Robert Lowe's scheme of "payment by results" could claim rank as a piece of wise statesmanship. The opening words of the "Prefatory Memorandum" show the cautious and reasonable spirit in which these suggestions are made:—

"In issuing this volume the Board of Education desire at the outset strongly to emphasise its tentative character, and to invite well-considered criticism designed to make it more useful for its special purpose."

The Blue-book contains an introduction on the objects of elementary schools, organisation, the curriculum, and the methods applicable to children of different ages, followed by chapters on the teaching of particular subjects, viz. English, arithmetic, observation-lessons and nature-study, geography, history, drawing, singing, physical training, needlework and housecraft, handicraft and gardening, and hygiene. Specimen schemes for most of these subjects are given as a series of appendices.

The suggestions made for arithmetic are of a wise and practical kind, as a few extracts will show:—

"The instruction in arithmetic should be made as realistic as possible. . . . The use of sets of objects will make it possible from the very beginning to teach the children to add, rather than count by units. . . . Multiplication tables should not be learnt before they have been constructed and understood. . . . Every school should be provided with (*a*) foot-rulers graduated. . . (*b*) cords with feet, yards and metres marked upon them, . . . (*d*) a pair of common scales with the smaller weights . . . (*e*) measures of capacity . . . (*f*) squared paper or tracing cloth. . . . The commercial applications of arithmetic commonly found in text-books could be advantageously replaced by algebra, practical geometry and the mensuration of the simpler solids and surfaces."

The chapter on observation-lessons and nature-study emphasises the importance of training in accurate observation and accurate description. The distinction made between the two terms is that observation-lessons are for children under ten, while nature-study is for older ones. This seems an artificial distinction, apparently involving the thesis that by the tenth year there is nothing left for observation by the pupils in elementary schools except the outdoor world. The movement of late years for nature-study has, in fact, involved a confusion of thought between subject-matter and method; and it has come to pass that on the one hand didactic teaching of elementary botany, provided it is accompanied by practical verification, and on the other almost any sort of heuristic teaching, are equally covered by that vague and comprehensive term. We see some trace of this confusion of thought in the following remarks:—

"The main factor which marks off nature-study from other school subjects should be that in it the instruction proceeds solely from the actual object, and never from description or reading. In practically every other subject, no matter how successfully the teacher makes the scholar look for the information he requires, the child has to take things for granted, and must depend on the good faith of the teacher or of the printed book; in nature-study comes the opportunity of proceeding by another method and teaching from the thing itself. The teacher should then be very jealous not to waste this unique opportunity" (pp. 48–49).

If this be interpreted as an attempt to use nature-study as an heuristic wedge to be driven into densely didactic school traditions, we may approve of its practical purpose; but with the more idealistic tone of the whole book it is inconsistent. The whole of the chapter on arithmetic is saturated with the notion of "teaching from the thing itself." So far from

[1] "Suggestions for the Consideration of Teachers and others concerned in the Work of Public Elementary Schools." Pp. 156. (1905.)

nature-study affording an unique opportunity for heuristic teaching, the very complexity of the problems which its subject-matter presents puts it at a disadvantage as compared with the simpler problems of elementary physics and chemistry.

Again, how can we reconcile the foregoing quotation with the following, which precedes it by a few pages?

"When a dog has been used as the subject of an observation lesson, the children may read, or be told, about the wolf or the fox. This will lead them to compare and contrast, and will aid in stimulating imagination" (p. 46).

Must we say that the dog is part of "nature" while the wolf and fox are not? or that methods bad for children over ten are allowable below that age? or must we simply explain the difference as due to composite authorship, permissible in a book of suggestions (not instructions), coupled with some confusion of mind on the part of one author between method and subject-matter?

The true idea of the relative positions which heuristic and didactic methods should occupy, which to our mind is well illustrated by the above simple case of the dog and the wolf, is clearly expressed in the chapter on geography:—

"In order that the study of geography may be of real educational value it must not be regarded as a process by which certain facts about the earth . . . are committed to memory. It must be rather regarded as the subject, which above all others brings the youngest child as well as the most advanced student into contact with the outside world. . . . It is true that as we advance in the study of geography we have to rely, to a great extent, upon the investigations of others, but in order that they may understand these investigations we must from the very first teach children to work for themselves and to take nothing for granted."

Nevertheless, it is not suggested that early geographical teaching shall be purely heuristic. On the contrary, the value of stories of strange and distant countries is strongly urged. At first these are scarcely differentiated from fairy-tales, but with each succeeding year they become more exact, until they at length pass into definite geographical teaching for which an observational basis has meanwhile been prepared. Here we see a development of the idea of the relation between didactic and heuristic teaching. It is useless and unnecessary to think, even as a remote ideal, of the exclusion of the former; all that is necessary is to prevent it from being more precise in character than is justified by the stage attained in the latter.

History, in spite of authoritative opinion to the contrary, we must regard as a science, but one in which heuristic teaching is out of the question. Like the one side of geographical teaching, it grows out of fairy-tales, and there need be no scruple in telling young children traditional stories that have not survived modern critical research. But we are glad to see that visits to local places of historical interest are recommended, and that in one at least of the schemes suggested in the appendix the syllabus for the highest class includes "first notions on the materials of history and the use of evidence." Unfortunately, very few teachers will have had any opportunity of acquiring the necessary knowledge on this subject. A book treating in a simple manner of the materials of history—and by no means confined to the documentary portion—is much to be desired.

To sum up the ideas we have so far gathered, we venture to think that in some future edition of these "suggestions" the division into subjects will perhaps be largely abandoned, and in its place we shall have a division by methods which will by no means coincide with groups of the present subjects. Even the official time-tables may come to recognise this. On the one hand we shall have heuristic teaching, aiming primarily at training the mind in scientific habits of thought, and incidentally imparting knowledge; on the other hand, didactic teaching to impart knowledge which is wanted but cannot be obtained at first-hand—its scope being carefully adapted to the stage reached in heuristic training. But, alongside of these two methods, there still remain a number of other subjects, which do not fall under either of these heads, since they consist in training or drilling of some description, *e.g.* the use of the mother tongue, singing, handiwork, and health-training. This last, we agree with the writers of the Blue-book, it is not advisable to teach to young children on a physiological basis. Hygienic habits must be learnt before the age at which physiological laws can really be understood, since some knowledge of physics and chemistry is essential to their real understanding; and to attempt to teach them without such a basis is only to give false knowledge, which is only too likely to prevent the acquisition of true knowledge in later years.

A. M. D.

A NEW ULTRA-VIOLET MERCURY LAMP.

UNDER the name of "The Uviol Lamp," Dr. O. Schott, of Jena, is introducing a modification of the Cooper Hewitt mercury vapour lamp, which appears likely to prove useful. The illuminating power of these lamps is very high, and the arc is very rich in ultra-violet rays, but the glass envelope hitherto prevented the passage of many of these actinic radiations. Dr. Zchimmer has recently produced at Jena glasses which are pervious to the ultra-violet rays, and Dr. Schott has made the envelope of the new lamp of this material.

The Uviol lamps consist of tubes of this special glass of 8 to 30 millimetres diameter and 20 to 130 centimetres length. Platinum wires are fused into the extremities, terminating in carbon heads. In the glass tube there is a charge of mercury of 50 to 150 grs., according to the size. The lamps of various sizes, with their resistance and choking coils, can be connected with electric mains of 220 or 110 volts.

To start the arc, the lamp is tilted to a sufficient degree to allow of the mercury in the tube passing from one pole to the other. At the moment of contact between the pole and the mercury, part of the latter is disintegrated simultaneously with the formation of a column of light. The carbon and heads to the poles permit the passage of the current in either direction without fusing the platinum poles. To get the best results from a current of 220 volts the lamp tube must be 130 centimetres long, but two or three suitable shorter lamps may be arranged side by side or one behind or over the other.

The spectrum of the Uviol lamp is exceedingly rich in lines. The lamp is particularly suitable for taking photographs and for copying processes by artificial light. Experiments have also been made in testing by its means if certain colours used in dyeing and printing have sufficient power to resist the fading effects of the sun. It will thus prove of value in rapidly settling the question of the fastness of colours, which will in future require days instead of months.

The Uviol lamp is also a germicide, and it appears likely that it will prove of value in the treatment of certain diseases of the skin. It is an irritant, and easily sets up inflammations, particularly of the eyes, so that the greatest care must be taken by operators

by means of suitable spectacles. With tactful handling it is said that the Uviol lamp can be used for 1000 working hours without loss of efficiency. The cost of a 400- to 800-candle lamp is 1*d.* to 2*d.* per hour. It thus appears to be a very economical method of converting electrical energy into efficient radiating energy of short wave-length.

NOTES.

THE opening of the bridge over the Victoria Falls on September 12, and the visit of the British Association, were celebrated by a banquet, at which Mr. Newton, representing the British South Africa Company, in proposing the health of Prof. Darwin, welcomed the association on the anniversary of the first occupation of Mashonaland by pioneers fifteen years ago, fifty years after Dr. Livingstone first saw the falls. Prof. Darwin proposed the toast of Sir Charles Metcalfe, representing the great enterprise which to-day marks an important step in advance. Reuter's Agency reports that Sir Charles Metcalfe, in the course of his reply, read congratulatory telegrams from Lord Grey and the directors of the British South Africa Company, and a telegram from Mr. Reunert, president of the South African Association of Sciences, conveying his congratulations that more links had been formed in the chain of civilisation. On September 15 the association received a hearty welcome at Salisbury (Rhodesia). The town was decorated, and the trains were met at the station by the local authorities, headed by the Mayor, the Acting Administrator, and the Resident Commissioner. At a subsequent luncheon the Mayor, in welcoming the members of the association to the most northern part of their tour in South Africa, directed attention to the progress made since the occupation of Rhodesia fifteen years ago. When the many diseases which affect the cattle of the country have been conquered, it is hoped that stock-raising will develop very rapidly. In the course of his reply, Prof. Darwin remarked that when the papers and lectures dealing with the special features of South African scientific work are published, it will be seen that serious efforts have been made to grapple with these problems. Sir Thomas Scanlen welcomed the association on behalf of the Chartered Company; and Lord Rosse and Sir William Crookes also spoke. On September 16, at Umtali, a deputation headed by Senhor de Sousa, secretary of the Governor of Mozambique, met the section of the British Association proceeding to Beira. Senhor de Sousa welcomed the members of the association to Portuguese territory in the name of the Governor, the Mozambique Company, and the inhabitants of Beira. On September 17, at Beira, the visitors attended a reception given by the Governor, and were entertained at luncheon. At 4 p.m. on the same day the party left for home on the steamer *Durham Castle*. We regret to learn that Sir William Wharton, a member of the British Association party which is returning home *viâ* Cape Town, is lying ill at the observatory there, having contracted a serious chill.

FOR the past two years cholera has steadily been proceeding westward, and during 1904 had manifested itself in Asiatic Turkey, Persia, and Russia. Since then cases have been recognised in Germany and Austria, and already 179 cases, with 65 deaths, have been recorded in Prussia. A considerable responsibility, therefore, rests on our frontier guards, the port sanitary authorities throughout the kingdom, particularly in view of the number of aliens who reach our shores from the region of the infected districts. If cholera unhappily should reach us, it is not likely to cause any serious epidemic. The last epidemics of note in this country were in 1828, 1848, and 1859.

IT is announced in the *Bulletin de la Société d'Encouragement* that next month a museum of industrial hygiene will be opened in Paris by the President of the Republic. The creation of the museum was authorised by a decree of December 24, 1904. Accommodation for the museum has been found at the Conservatoire des Arts et Métiers, and the sum of 41,000 francs considered necessary for the installation has been collected, as well as subscriptions to cover the annual cost of upkeep. The exhibition will be a permanent one, and, being a loan collection, will be constantly renewed.

THE sixth congress of criminal anthropology will meet at Turin on April 28, 1906, under the presidency of Prof. Lombroso. An exhibition of criminal anthropology will be held in connection with the congress.

DR. OSCAR MAY died at Frankfort-on-the-Main on August 25 at the age of fifty. Dr. May (says the *Electrician*) was one of the founders of the Elektrotechnische Lehr- und Untersuchungs-Anstalt of Frankfort, and was until 1895 instructor in electric lighting at that institution. At the Frankfort Exhibition in 1891 he was a member of the presiding committee and one of the secretaries of the scientific commission.

WE learn from the *Victorian Naturalist* that the estimates recently presented to the council of the University of Melbourne contain, among other proposals of a scientific nature, provision for the erection of a botanical laboratory and the appointment of a professor of botany, who, it is proposed, shall also act as Government botanist. This arrangement, remarks our contemporary, should ensure the best use being made of the valuable collection of Australian plants in the National Herbarium.

A LETTER from Prof. David Todd, dated September 8, informs us that the print of the solar corona of August 30 which was reproduced in last week's NATURE (p. 484) was from an early developed negative done during the heat of the Sahara *gibleh*, and was inferior to others developed after the weather turned cool again. He sends us one of these original negatives, which shows a large amount of detail that did not appear in the print reproduced in NATURE. The automatic machine with which these exposures were made took about seventy-five negatives during totality, of which sixty-three proved to be useful for executing drawings of the corona.

DURING the past few days earthquake shocks have been felt in various parts of Italy. The following is a summary of Reuter messages published in the daily papers:—*September* 13, *Innsbruck*.—Severe shock felt in the Arlberg district at 1.30 a.m. Duration, from six to ten seconds, and direction from south to north. *September* 14.—Shock felt at 10.10 a.m. at Racidena, Messina, Reggio di Calabria, and Mineo; recorded on the seismic instruments at all the observatories in Italy. Another shock felt at Reggio (Calabria) at 12.33. *September* 15.—Mount Vesuvius is becoming increasingly active. During the day frequent undulatory shocks were felt in the region around the volcano. The activity of Stromboli is also very remarkable. *September* 16, *Innsbruck*.—Severe shocks felt in the Arlberg district at 4.3 a.m. and 4.37 a.m. First shock lasted five seconds and the other four. The shocks were accompanied by loud rumblings. *September* 17, *Monteleone*.—Shock felt at 1.40 p.m.

September 18.—Sharp earthquake shocks were felt at 3 a.m. and 11.15 a.m. at Reggio (Calabria). Further damage was done in the provinces of Catanzaro and Cosenza. A severe shock was felt at Monteleone.

THE deaths of two well known explorers were announced in the *Times* of Saturday last. M. de Brazza died at Dakar on September 14 in his fifty-third year, and Captain J. Wiggins at Harrogate on September 13 in his seventy-fourth year. De Brazza was sent in 1875, accompanied by Dr. Ballay and M. March, naturalist, to explore the Ogowe, the great river in Gabun in Equatorial West Africa. During the succeeding eight years he laid the foundations of the French Congo Protectorate. A second visit to West Africa, which lasted for three years, was made in 1879, and during this time de Brazza persuaded King Makoko to place himself under the protection of the French flag. Successive journeys were made to the same regions in 1883 and 1887. After an expedition in 1891–2 from Brazzaville to the Upper Sungha with the view of opening up a route to the Shari and Lake Chad, de Brazza settled down in France. Last April he was sent out as commissioner to inquire into the charges of maladministration in French Congo territory, but the hardships incident to travel in the malarial tropics of Africa this time proved fatal. To Captain Joseph Wiggins belongs the credit of having discovered, or at least rediscovered, thirty years ago a new ocean highway within the Arctic circle by which the trade of European Russia obtained for the first time direct maritime access to the navigable rivers of Siberia. Captain Wiggins was a Fellow of the Royal Geographical Society.

THE thirteenth annual exhibition of the Photographic Salon is now open at the Gallery of the Royal Society of Painters in Water Colours, Pall Mall East. It contains many very fine examples of photography which will interest the scientific student in showing what can be done by means of modern methods. The aim of the promoters of the exhibition is purely pictorial, and although presumably all the works shown are produced by photographic means, it is obvious that there is some, and in a few cases probably a great deal of hand-work in addition. This detracts to a certain extent from the value of the representations of the various phases of nature, of which there are several interesting examples. The methods employed are quite outside the consideration of the society responsible for the show; we can therefore only surmise that the majority of the multi-coloured pictures, and there are about a dozen of them, are made by the gum-bichromate process, applying from two to five coatings of different colours as desired. But the portrait of Frederick Hollyer by Mr. F. T. Hollyer is probably printed on platinum paper, the colours being obtained by modifications in the method of development or by subsequent treatment of the print. A picture so made is obviously not a platinum print, and its permanency and other characteristics must depend entirely upon the nature of the pigmentary materials present. We do not notice any example of "photography in natural colours" as this phrase is commonly understood.

THE greater part of the *Naturwissenschaftliche Wochenschrift* for August 27 is devoted to a review, by Dr. Thesing, of the pathogenic protozoa, dealing particularly with the subject of syphilis.

THE *Popular Science Monthly* for September contains many interesting articles. Messrs. Foulk and Earhart discuss State university salaries, and deplore the meagre remuneration of university teachers. If this be the case in America, how much more so is it in this country?

WITH reference to the article on "The Sterilisation of Water in the Field" (August 31, p. 431), the Lawrence Patent Water Softener and Steriliser Company writes to say that a mistake was made in the records of the official trials of water sterilisers, and that the Lawrence steriliser never consumes more than 1½ pints of kerosine per hour, not 2 pints as stated.

THE *Psychological Bulletin* for August (ii., No. 8) contains an important review by Dr. Meyer of Prof. Wernicke's monograph on aphasia, together with an obituary notice of Prof. Wernicke, who was killed on June 15 in a bicycle accident. We would suggest that the Bulletin be issued with cut pages in future.

THE *Revue de l'École d'Anthropologie de Paris* for August contains an article by MM. Capitan and Papillault on the identification of the body of Paul Jones 113 years after death. This was based partly on general characters, colour of the hair, &c., partly on measurements compared with those of certain contemporary busts, between which there was an extraordinary agreement, and partly on pathological details. There were clear indications of broncho-pneumonia, of tuberculosis, and of renal disease, and from contemporary records it is known that Paul Jones suffered from all of these.

LIEUT. CHRISTOPHERS, I.M.S., records a discovery of considerable interest, viz. the presence of a parasite belonging to the hæmogregarines in blood of the Indian field rat (*Gerbillus indicus*). Hitherto it has been believed that these parasites are confined to cold-blooded vertebrates. The parasite occurs as a motionless vermicule in the red blood cells, and as an actively motile vermicule in the plasma. Infection of the rat was proved to take place through its parasitic louse, a new species of Hæmatopinus, in which a developmental cycle is passed (*Sc. Mem. of the Gov. of India*, No. 18).

WE have received from the director of the Government Zoological Gardens at Giza, near Cairo, a list of a collection of animals obtained by the members of the staff during a collecting trip to the Sudan, which lasted from May 10 until August 10. The list comprises 129 animals referable to 46 species, among which a pair of Senegal storks are perhaps the most notable. It should be added that several of the specimens are the gifts of officials in the Sudan, and that a giraffe was confided to the care of the director by the Khedive.

To the first part of vol. ix. of the *Biological Bulletin* Dr. J. E. Duerden contributes a sixth instalment of his account of the morphology of the Madreporaria, dealing in this instance with the "fossula" of the extinct rugose corals. The fossula (of which there may be several), we may remind our readers, is a very characteristic feature of the Rugosa, and consists of a pit in the calice due to the smaller size of the vertical septa in that particular area. In this communication the author endeavours to explain the structure of this pit from the changes which take place in the corallite during development.

IN the August number of *Naturen* Mr. H. Schetelig describes, with illustrations, certain very interesting remains of buildings of Neolithic age which have recently been opened up in Scandinavia. The building takes the form of a portion of a curved wall situated in a stratum below the peat, which is itself overlain by a considerable

thickness of more recent deposits. Alongside the wall were found a number of stone implements, most of which are of the well known Neolithic adze type, although others are chiefly finished by chipping, and appear in some degree transitional between Palæo- and Neo-lithic types.

IN the first article of the August issue of the *American Naturalist* Prof. D. P. Penhallow discusses the ancestry of the poplars and willows (Salicaceæ) as deduced from the woody structure of the fully mature stem. The family appears to be of Old World origin, and while most of its Cretaceous representatives appear to have been suited to a warm climate, the tendency of the later forms appears to have been to adapt themselves to boreal conditions. The other articles include the seventh part of Dr. B. M. Davis's studies on the plant-cell, and a dissertation by Mr. J. A. Cushman on the developmental history of the shelled foraminifera of the group Lagenidæ. For the initial chamber of these lagenoids the author proposes the name "proloculum," on the analogy of "protoconch" in the case of the gastropod shell.

THE trustees of the British Museum have caused to be issued (at the price of 3*d.*) a special guide to an exhibition of old natural history books now placed in the main hall of the Natural History Museum in Cromwell Road. The object of the series is to illustrate the origin and progress of the study of natural history previous to Linnean times. Apart from reproductions of certain prehistoric sketches, which scarcely, it seems to us, come under the designation of "old natural history books," the series commences with Aristotle's natural history, followed by other works collectively assigned to the classical period. Arab philosophers, such as Serapion of the eight or ninth century, come next, and following these, after a brief reference to a few mediæval writers, we are introduced to the works of Leonardo da Vinci and the early "herbalists." With the close of the fifteenth century the legendary period of natural history gave place to an era of first-hand investigation, and special reference is made in the guide to Wotton (1492–1555), the first English physician to make a scientific study of the subject, and to whom belongs the credit of restoring zoology to the rank of a science. For the history of later writers and their works we must refer our readers to the exhibition itself, which, if studied by the aid of the excellent little guide before us, cannot fail to prove both interesting and instructive.

UNDER the conditions which prevail, it is too much to expect any great expansion of forest areas in the British Isles, but there is some consolation in the statement made by Mr. G. Pinchot, the energetic chief of the Bureau of Forestry in the United States, that the Canadian and Cape Colonies have established an efficient forest service, and that Australia and New Zealand are making progress in the same direction. Mr. Pinchot reviews the conditions of forestry in Germany, France, and Switzerland, also in British India and the United States, in the August number of the *National Geographic Magazine*. Among the illustrations are some depicting the employment of elephants in the teak trade of Burma.

AN account of the Erysiphaceæ of Japan in the *Annales Mycologici*, vol. iii., No. 3, by Mr. E. S. Salmon, affords some instances of distribution which are not readily explained. Four species were previously only known from America, one each from Australia and China, and five are endemic. One species, *Uncinula geniculata*, was gathered near Tokio on an endemic plant, *Styrax Obassia*; as recorded from America, the only host-plant is *Morus rubra*. Mr. Salmon suggests that possibly *Morus rubra* will be found to exist in Japan, or that the area of distribution of the two host-plants may have overlapped, or that the fungus, having been introduced to Japan, has spread to a new host-plant.

THE sixteenth annual report of the Missouri Botanical Garden contains three papers on fungal diseases observed on cauliflowers by Dr. H. von Schrenck and Mr. G. G. Hedgcock. Following upon the treatment of the cauliflower leaves with different fungicides, it was noticed that swellings were raised in certain cases; further experiments proved that these were caused by the application of a solution of copper ammonium carbonate which induced extravagant enlargement of the mesophyll cells. Prof. Sorauer, who has treated the subject of intumescences very fully, has referred their formation to the action of an abnormal elevation of temperature, combined with excessive water supply. In the experiments here detailed these conditions did not obtain, and Dr. Schrenck shows definitely that the swellings are the result of chemical stimulation brought about by the copper ammonium salt when applied in a dilute solution, and he compares it with the well known action of poisonous salts, which in weak solutions induce acceleration of growth.

THE August number of the *Fortnightly Review* contains an article by Mr. W. H. Mallock on the two attacks on science. The two attacks are the clerical and the philosophic, and the writer contends that the former of these has failed entirely, because man and the universe, when studied as modern science studies them, neither can have, nor require to have, any other explanation than that which science offers us, the principle, namely, that all phenomena result from a single system of interconnected causes. There are no longer gaps in which the divine interference can be seen, for even the gap between the organic and the mental has been bridged over by the discovery that consciousness and mind are by no means co-extensive and identical, *i.e.* that consciousness is not essential to the existence and operations of mind. As for the philosophic attack, the main problem is that of the origin of ideas, and Mr. Mallock accepts the scientific view that the mind is a highly complex organism, having a long pedigree, and evolved from simpler elements; that the "connection of things" gradually reproduces itself in the "connection of ideas"; that the individual is at no point to be regarded as separated from the cosmic whole, but that even conation, which has sometimes been supposed to differentiate mental from other processes, depends on the universal conation of nature. On these lines science extends indefinitely the borders of what we call self, and breaks down the dividing line between ourselves and the universe; and thus introspective philosophy "instead of disintegrating science as a system of childish materialism, merely hardens and sublimates it into a system of universal mentalism."

WE have received an effective relief map of the Dominion of Canada, on a scale of 100 miles to an inch, published by the Department of the Interior.

A RECENT Bulletin (No. 15) of the Geological Commission of Finland contains a series of chemical analyses of ninety-one igneous rocks from Finland and the Kola peninsula. The analyses are set out and the rocks classified according to the elaborate new method of the American petrographers (Whitman Cross, Iddings, Pirsson, and Washington), in whose work many of these analyses have already appeared. Thirty-eight, however, are new, being mostly the work of Miss N. Sahlbom.

THE Geological Survey continues its work of unravelling the complex structure of the Highlands, and has lately published a memoir on the region of the Upper Tay and Tummel valleys (Sheet 55, Blair Atholl, Pitlochry, and Aberfeldy), a region where the newest and the oldest of geological formations alone are found. Most of the memoir is occupied with the field relations and petrography of the crystalline schists and igneous intrusions, but glacial and alluvial deposits are also described. Chief among the illustrations are seven very fine photographic plates. One of the most interesting is a view of the rocky bed of the Garry, with the curious "water-pipe" structure, due to unsymmetrical folds in the Moine gneiss. An example of the practical utility of the survey is given in the fact that the basalt quarries near Aberfeldy, which supply the best road-metal in the district, were started at the suggestion of a survey officer.

THE Geological Survey of Ireland has recently been transferred from the charge of the Board of Education to the Department of Agriculture and Technical Instruction, and in connection with the transference an interesting article describing the survey's history and work has been contributed by Prof. Grenville A. J. Cole to the department's journal. In this article mention is made of the fact that so long ago as 1837 a laboratory for the examination of soils was established in Belfast, and a soil survey was projected. Unfortunately, however, the authorities were unsympathetic, and Ireland has not the credit of the first soil survey. "It was left," writes Prof. Cole, "for Germany, the United States, Japan and other countries to develop agricultural geology as a branch of organised research." Under the care of Sir Horace Plunket's vigorous department, it is safe to predict that the survey will now make amends to Irish agriculture for the neglect of 1837.

WE have received the report of the United States Geological Survey on the results of primary triangulation and primary traverse for the fiscal year 1903–4, by Mr. S. S. Gannett. Prefixed to this is a valuable chart showing the "condition of astronomic location and primary control" in the United States up to April 30, 1904.

THE new number (vol. xviii., part i.) of the *Mitteilungen aus den deutschen Schutzgebieten* contains a paper of interest to surveyors on a method of measuring a base-line, in sections of about 40 metres, by means of a 4-metre subtense rod and theodolite, by Herr H. Böhler. The reduction of the observations is dealt with in detail, and Captain Kurtz contributes a separate note on a special method. The general result points to an error of about $\pm 7 \cdot 4$ mm. per kilometre.

WE have received No. 8 of the "Current Papers" presented to the Royal Society of New South Wales. Nearly two years have elapsed since the last of these papers was communicated by Mr. H. C. Russell, F.R.S., and on account of his illness the present number has been drawn up by Mr. H. A. Lenehan, the acting Government astronomer for the State. The Federal postal regulations having done away with the system of "franks" for Government documents, the number of observation records received diminished by about 60 per cent. in 1904 as compared with the average for the period 1899 to 1903. Several records are, however, of great interest, notably that of a float cast adrift off the coast of California, and picked up on the island of Boillon in the Java Sea, after a journey of 11,350 miles.

STANDARD sections for rolled iron were used first in Germany in 1879 and in the United States in 1897. In Great Britain the Engineering Standards Committee was appointed in April, 1901, by the Institution of Civil Engineers, the Institution of Mechanical Engineers, the Iron and Steel Institute, and the Institution of Naval Architects to inquire into the advisability of standardising rolled iron and steel sections for structural purposes; and although the time has not yet been sufficient for the standard sections to be adopted as widely as they are in Germany, the committee has done admirable work, and with the support of the Institution of Electrical Engineers important developments are being made in other fields. The latest reports received, namely, No. 16, "British Standard Specifications and Tables for Telegraph Material" (London: Crosby Lockwood and Son, 1905, price 10*s*. 6*d*. net), and No. 23, "British Standards for Trolley Groove and Wire" (London: Crosby Lockwood and Son, 1905, price 1*s*. net.), are striking examples of the wisdom displayed by the committee in not going too far in the direction of standardisation. In the case of telegraph material it is not considered necessary to issue a specification for copper wire. No attempt has been made to standardise submarine or underground tables, nor telegraphic or telephonic apparatus; and in the case of trolley wire it has not been deemed advisable to go further in the direction of standardisation than the recommendation of certain figures for the minimum tensile breaking strength for the gauges of wire in general use. No attempt is made to standardise any particular design of trolley wheel, the committee having confined itself to recommending a groove of a certain section. In short, these standard specifications are so reasonable that they cannot fail to meet with general adoption, as economy in production is ensured without any revolutionary change or any restraint on originality of design.

AT the last meeting of the Faraday Society (held on July 3) a paper was presented by Prof. E. Wilson upon "Alternate Current Electrolysis." The author has carried out a long series of experiments with alternating currents, using various metals as electrodes, and various metal salt solutions as electrolytes. The loss or gain in weight of the electrodes during the experiments was recorded, and accurate measurements of the potential difference and of the current intensity were also made. The exact potential difference between the electrodes was obtained by use of an exploring electrode placed between the plates and a quadrant electrometer. The following metals were experimented with:—lead, zinc, iron, copper, tin, and aluminium. The frequency of the alternating period, the density and character of the electrolyte, and the current intensity were varied during the experiments with each metal. The results obtained are gathered together in tabular form in the original paper, and these show that the loss of weight was greatest in the case of lead in a dilute sulphuric acid solution, and least in the case of copper. The discussion on this paper has been adjourned until the meetings of the society are resumed in November next.

THE Cambridge University Press has just published an index to the volume containing Lord Kelvin's "Baltimore Lectures on Molecular Dynamics and the Wave Theory of Light," reviewed in NATURE of May 5, 1904.

A FOURTEENTH edition of "Mineralogy," by the late Mr. Frank Rutley, has been published by Messrs. Thomas Murby and Co. The book has been revised and corrected, and a brief notice of the radio-active elements, contributed by Mr. Ernest H. Adye, has been added.

COPIES of two booklets, which have been published privately by Mr. F. W. Armstrong, of the Blue School, Wells, Somerset, have been received. They deal respectively with elementary inductive chemistry and inductive physics.

A NEW catalogue of physical and electrical instruments, balances, &c., has been issued by Messrs. W. G. Pye and Co., of the "Granta" Works, Cambridge. The excellent illustrations, drawn to a larger scale than is usual in similar publications, should greatly assist customers ordering instruments from a distance, since with the accompanying concise explanations little room is left for misapprehension.

OUR ASTRONOMICAL COLUMN.

THE VARIABLE ASTEROID 1905 Q.Y.—From a telegram from Dr. Palisa to the Kiel Centralstelle, it appears that the asteroid which, on the supposition that it was a newly discovered one, was designated 1905 Q.Y., is identical with that known previously as (167) Urda. The identity is confirmed by Prof. Berberich, who writes that on August 28 the magnitude of Urda was from 0·5m. to 1·0m. brighter than shown by the value given in the Jahrbuch (*Astronomische Nachrichten*, No. 4046).

NOVA AQUILÆ No. 2.—From a note in No. 4046 of the *Astronomische Nachrichten*, we learn that the position first given for Nova Aquilæ was 1m. wrong in R.A. It should have read R.A.=284° 17′ (=18h. 57m. 8s.) instead of 284° 2′ as given, the mistake occurring in the first telegram received at Kiel.

Observing this object on September 5, Prof. Hartwig determined the position, referred to the equinox of 1905·0, as R.A.=284° 16′ 16″ (=18h. 57m. 5·06s.), dec.=−4° 34′ 50″, and found the magnitude to be 10.

FRENCH OBSERVATIONS OF THE TOTAL SOLAR ECLIPSE.—No. 10 (September 4) of the *Comptes rendus* contains the brief reports received from various French eclipse expeditions by the Académie des Sciences.

Prof. Janssen, M. Bigourdan, and MM. Stephan and Trépied, observing at Alcosebre, Sfax, and Guelma respectively, report satisfactory meteorological conditions and successful observations. At the last named place M. Bourget obtained fourteen negatives of the corona, using coloured screens. The parties at Cistierna, Burgos, and Tortosa were less fortunate, clouds interfering with, or totally preventing, observations. The measures of the ionisation of the electric field were, however, carried out throughout the eclipse by the observers at Tortosa. Similar observations were carried out, entirely according to programme and under perfect conditions, at Philippeville, and M. Nordmann, from a preliminary examination of the curves obtained, expects that some very interesting results will accrue when these are finally compared with those obtained on previous occasions. M. Salet, from the same station, reports that the polarisation of the corona was well observed, the deviation of the plane of feeble polarisation being 3°. Ten coronal radiations were photographed with a "Nicol" in front of the slit, and fifteen ultra-violet coronal radiations were photographed with the spectroscope.

From the eclipse station at Alcalá de Chisbert (Spain) M. M. Moye writes that the eclipse was observed under good conditions, and that the corona was very brilliant, the longest streamers occurring in the south and the north-east. The green line was very apparent. Shadow bands were well observed both before and after, but were invisible during, totality.

Observations of the partial phase were made in Paris, where the times of the contacts and of the occultations of spots were recorded by several observers. Unfavourable meteorological conditions prevented the actinometric observations, which it was proposed to carry out at Trappes, Bordeaux, and the Pic du Midi, from being made, but a series of good observations was obtained at Bagnères.

EYE-ESTIMATES OF THE TRANSITS OF JUPITER'S SPOTS.—In order to determine whether his own eye-estimates of the transits of Jupiter's spots were subject to any error similar to that suspected by Schmidt, the Rev. T. E. R. Phillips has analysed his observations, which number about 140, and cover the period of seven apparitions. As a result he has arrived at the conclusion that at the beginning of each apparition, when the planet's hour-angle is east, he observes the transit a little too early. Similarly, at the end of each apparition, when the hour-angle is west, the transits are recorded a little too late. The explanation of this error is that it is due to the varying slant of the belts as the planet is removed from the meridian, and the consequent failure of the eye to determine correctly the position of the line which bisects the disc and is normal to the planet's equator. If this explanation is correct, the error should be of the opposite sense in the two hemispheres, but the evanescent character of the spots in the northern hemisphere has prevented Mr. Phillips from making this test. Again, if the cause suggested is the true one, this error should disappear if care be taken to keep the line joining the eyes parallel to the belts.

In No. 361 of the *Observatory* Mr. Phillips gives the details of his observations during each opposition since 1898, and a diagram which shows the effect of the error referred to above on the observed drift in longitude of the Great Red Spot "Hollow." The hope is expressed that this may lead other observers to elucidate the matter further from their own experiences.

THE SOLAR ACTIVITY, JANUARY–JUNE.—No. 7, vol. xxxiv., of the *Memorie della Società degli Spettroscopisti Italiani* contains Prof. Mascari's usual summary of the solar observations made at the Catania Observatory during the first six months of the current year. A comparison of the "frequencies" observed with those recorded for the latter semestre of 1904 shows that the solar activity was much greater during the later period, but the increase was much more marked during the first quarter of this year than during the second. The daily frequencies of spots, faculæ, and prominences during the six months under discussion were 7·18, 7·12, and 3·29 respectively.

Two plates which accompany this publication show, diagrammatically, the sizes and positions of the prominences observed on the sun's limb at the observatories of Catania, Kalocsa, Odessa, Rome, and Zurich during the last quarter of 1902 and the first two months of 1903.

INSTITUTION OF MINING ENGINEERS.

THE sixteenth annual general meeting of the Institution of Mining Engineers was held at Manchester on September 13, 14, 15, and 16 under the presidency of Sir Lees Knowles, M.P. The report of the council contained an expression of deep regret at the loss sustained by the death of the president, Sir Lowthian Bell. The Institution of Mining Engineers is a federation of seven local mining societies—the Manchester Geological and Mining Society; the Midland Counties Institution of Engineers; the Midland Institute of Mining, Civil and Mechanical Engineers; the Mining Institute of Scotland; the North of England Institute of Mining and Mechanical Engineers; the North Staffordshire Institute of Mining and Mechanical Engineers; and the South Staffordshire and East Worcestershire Institute of Mining Engineers. Since the formation of the institution in 1889, the membership has increased from 1239 to 2901 in 1905.

The first paper read was on the leading features of the Lancashire coalfield by Mr. Joseph Dickinson, formerly H.M. Chief Inspector of Mines. This paper gave a concise summary of the recent developments of the geological investigation of the coalfield. Electric power distribution was dealt with in a paper by Mr. R. L. Gamlen, in which he showed the advantages possessed by the power companies as providers of power. Mr. B. H. Thwaite submitted a paper on colliery explosions in which he suggested, as a method of dealing with explosions, the installation of a series of pipes conveying a supply of oxygen and a pneumatic method of coal-dust removal. The former proposal met with much adverse criticism in

the discussion. Mr. Sydney F. Walker read a paper on earth in collieries, in which he pointed out some of the difficulties in carrying out the special rules drawn up by the departmental committee for the installation and use of electricity in mines. If earth was to be admitted into the system, the only method of carrying out the wishes of the committee was to use an uninsulated return completely enclosing the live conductor. The last paper read was by Mr. John T. Stobbs on the value of fossil Mollusca in Coal-measure stratigraphy. He expressed the opinion that Mollusca afforded the best means of correlating Coal-measures, and considered that their neglect was due to inadequate collections in public museums, and to the fact that teachers failed to impress upon students the utility of the Mollusca as zonal indices. The Coal-measures were, he thought, comparatively neglected by the geologist, the knowledge of the Ordovician, Silurian, and Chalk systems being much more exact than that of the 3000 feet of Coal-measures. The remaining days of the meeting were devoted to excursions to Chanters Colliery, to New Moss Colliery, to the Manchester Museum, to the works of the British Westinghouse Company and the Manchester Ship Canal, to Pendleton Colliery, and to other places of interest.

THE BRITISH ASSOCIATION.

SECTION K.

BOTANY.

OPENING ADDRESS[1] BY HAROLD WAGER, F.R.S., H.M.I., PRESIDENT OF THE SECTION.

ON SOME PROBLEMS OF CELL STRUCTURE AND PHYSIOLOGY.

Introduction.

WHEN Robert Hooke, in the early part of the seventeenth century, discovered, with the aid of his improved compound microscope, the cell structure of plants, he little thought that our ultimate knowledge of the physical and chemical processes in the living organism, of its growth and reproduction, of the problems of heredity and of the factors underlying the origin of life itself, would be in the main dependent upon a clear understanding of the structure and physiology of the cell.

Hooke's researches did not, in fact, carry him very far, and we must turn to the nearly contemporaneous works of Malpighi and Grew on the anatomy of plants for the first clear indication of the important part which cells take in the constitution of the various tissues of plants. The account they give of them is extremely interesting in the light of our present knowledge. Grew, for example, in speaking of the structure of the root, compares the parenchyma to a sponge, "being a body porous, dilative, and pliable . . . a most exquisitely fine wrought sponge." The pores are spherical and consist of "an infinite mass of little cells or bladders. The sides of none of these are visibly pervious from one into another; but each is bounded within itself. . . . They are the receptacles of liquor, which is ever lucid, and . . . always more thin or watery." There is no indication either in Grew's or Malpighi's works that they understood the significance of this cell structure, and it was not until the beginning of the nineteenth century, after a lapse of some 150 years, that any insight into the real nature of the cell and its functions was obtained. But then began a period of activity—associated with the names of Turpin, Meyen, Robert Brown, Purkinje, J. Müller, Henle, Valentin, and Dutrochet—which culminated in the cell theory of Schleiden and Schwann that the common basis of all animal and plant tissues is the cell, and that it is upon this elementary vital unit that all growth and development depends.

The nucleus was discovered in 1831 by Robert Brown in various tissues of the Orchideæ and in some other families of the monocotyledons, as well as in some dicotyledons. He described it as a "single circular areola, generally somewhat more opaque than the membrane of the cell," and more or less granular. It is very distinct and regular in form, and its granular matter is held together by a coagulated pulp not visibly granular, or, which may be considered equally probable, by an enveloping membrane. Although Robert Brown was the first to recognise the importance of the nucleus, and to give it a name, it had been seen by previous observers, and he himself mentions that he had met with indications of its presence in the works of Meyen and Purkinje, chiefly in some figures of the epidermis; in a memoir by Brogniart on the structure of leaves, and that Mr. Bauer had particularly noticed it in the cells of the stigma of *Bletia tankervilliae,* but had associated it with the impregnation by pollen. There are some figures by Leeuwenhoek, published in 1719, to which Prof. L. C. Miall has directed my attention, of blood-corpuscles of a fish, human epidermal cells, and the connective tissue of a lamb, in which nuclei are shown, and they had been seen by Fontana (1781) in epithelial cells, and by Cavolini (1787) in some fishes' eggs.

To Schleiden and Schwann the cell was essentially a membranous vesicle enclosing a fluid sap and a solid nucleus. They thought that it arose in contact with the nucleus as a delicate transparent vesicle which gradually increased in size and became filled with the watery sap. As soon as it was completely formed, the nucleus, having done its work, was either absorbed or cast off as a "useless member," or in some cases was "found enclosed in the cell-wall, in which situation it passes through the entire vital process of the cell which it has formed." So far from being the most important organ of the cell, as we now consider it to be, they saw in the nucleus merely a centre of cell formation which is no longer required when the cell is formed. It was left for Hugo von Mohl to show that the mucus-like contents of the cell which he called protoplasm (1846) is the real living matter in which reside those activities which call into play the phenomena of life, and that the origin of nuclei by division from a nucleus already existing in the parent cell would possibly be found to occur very widely. Von Mohl, Nägeli, and Hofmeister all appear to have had some idea of the importance of the nucleus in cell division. Von Mohl says that the "process is preceded in almost all cases by a formation of as many nuclei as there are to be compartments in the mother-cell." Hofmeister's description of it is interesting: "The membrane of the nucleus dissolves, but its substance remains in the midst of the cell; a mass of granular mucilage accumulates around it: this parts, without being invested by a membrane, into two masses, and these afterwards become clothed with membranes and appear as two daughter-nuclei."

It is, however, mainly to the researches of the last thirty years that we owe our knowledge of the many complex cell-activities at work in living organisms, and we are still only just on the fringe of the great problems which cytology has to solve. Some of the most important of these are the origin and evolution of the nucleus, the meaning of the complex mode in which the nucleus divides, the origin and nature of the spindle figure and centrosomes, the part played by the chromosomes in the transmission of hereditary characteristics, the meaning of the phenomena accompanying fertilisation, the significance of the longitudinal division of the chromosomes and of their reduction in number in the sexual cells, and the evolution of the living substance. The satisfactory solution of these problems depends upon a clear understanding of the structure of protoplasm and its various differentiations. How far we have succeeded in obtaining this I will endeavour to show.

The Differentiation of Structure in the Cell.

The essential constituent of a cell is the protoplasm. This is differentiated into two constituents, the cytoplasm and the nucleus. It is usually held that this differentiation is an essential one, and that these two constituents are present in all cells; but, as we shall see later, there is some evidence that not only are there cells with very rudimentary nuclei, but cells in which no trace of a nuclear structure can be found at all.

In addition to this primary differentiation of the cell, secondary differentiations occur, resulting in the production of organs such as chloroplasts, chromoplasts, leucoplasts, pyrenoids, and pigment spots, which have special

[1] Slightly abridged.

functions to perform. All these are permanent organs of the cell, produced in the first instance as a result of the cell activity, but now capable of an independent existence in the cell, in that they reproduce themselves by division, and are in this way carried on from cell to cell.

In many cells there are formed at certain stages other organs which appear to be transitory, and are only produced when they are required. Such are the spindle figure, the centrosome, the blepharoplast, and the cœnocentrum.

So far as we know, the cell is the smallest vital unit that can have a separate existence. But it is only among the unicellular organisms and under certain conditions in the earlier stages of development of the more highly organised multicellular organisms that cells have a perfectly independent life. Schwann's hypothesis that the multicellular body is a colony of independent vital activities governing the nutrition, growth, and reproduction of the whole is not tenable. The cell cannot be regarded as an independent unity working merely in association with other cells. Its life and existence depend upon these. It is an integral part of an individual organisation, and cannot exist apart from it. But this absolute dependence of individual cells upon the organisation as a whole is only realised in the more highly developed forms. In the lower types of plants (and animals) it is possible, during the early stages of development, to separate a single cell from the whole, which will still continue to live and grow. Each cell is no doubt dependent upon the others to some extent, even at this early stage, but it still retains the power to develop independently if placed under suitable conditions. As cell division continues each cell becomes more and more dependent upon its fellows, until the stage is reached when it no longer has the power to exist by itself. The various functions performed by a cell reside within it as an individual unit, but the exercise of these functions is governed by the organism as a whole. Just as the organism seeks for a state of equilibrium in relation to various external stimuli, so a cell in an organism has to adapt itself to and come into a state of equilibrium with the various cells around it.

The Nucleus.

The nucleus is the centre of activity, and governs the vital functions of the cell. All investigations show that in its absence the cell soon ceases to perform its vital functions and dies.

In all cells, from the algæ and fungi upwards, the nucleus is more or less clearly delimited from the cytoplasm by a membrane or limiting layer. The important substance which is thus separated off from the rest of the cell is the chromatin, probably the most complex and most highly differentiated chemical compound or collection of compounds in the cell. It exists in the form of a more or less granular network, and is characterised chemically by the presence of phosphorus, which is in organic connection with it. We may look upon the chromatin as the highest point in the development of living substance, upon which the activities of the cell in great measure depend, and as the seat of origin of all those complicated changes which have for their ultimate aim the division of the cell.

The division of the nucleus begins by a series of transformations in the chromatin network which lead to the differentiation in it of chromosomes. We know very little of what actually takes place during these changes, and practically nothing of the forces at work to bring them about. But the visible result is that the chromatin granules gradually fuse together, or become restricted to certain areas by the increased vacuolation of the ground substance of the nucleus to form a thick, more or less regular thread, in which can be observed at certain stages a differentiation into alternate regions of stainable and unstainable substance—chromatin and achromatin—which finally breaks up into equal or unequal lengths to form the chromosomes. In some cases the chromatin granules or network become aggregated into a definite number of irregular masses which form the chromosomes directly without the production of a distinct chromatin thread.

This nuclear differentiation is usually accompanied by changes in the cytoplasm which lead to the appearance of a fibrillar structure in the form of a more or less regular spindle, the threads of which come into contact with the chromosomes through the breaking down of the nuclear wall. The chromosomes then, by the action of a force or forces of which we as yet know very little, arrange themselves in regular order in the equatorial plane of the spindle figure, and some of the spindle fibres become attached to them. The chromosomes become divided longitudinally into two apparently exactly equal halves; and then, probably by the exertion of some sort of contractile force or pull on the part of the spindle fibres, the separate halves are caused to move to opposite poles of the spindle. Here a series of transformations take place, which lead to the constitution of two new nuclei. Such are the essential features in this complex process of nuclear division, and it is a striking fact that they occur with more or less regularity in all nuclei from the algæ and fungi up to the highest plants.

The Structure of Cytoplasm.

In the elucidation of cell structure we owe much to the beautiful methods of staining and fixing which are due especially to Flemming and Heidenhain, to the improved micro-chemical methods which we owe especially to Zacharias and Macallum, and to the investigations of such observers as Fischer and Mann, who have shown us the effects of various reagents upon the living substance, and have thus taught us to be very cautious in our interpretations of the structures seen in dead fixed cells.

The investigations of oil-foams and colloids by Butschli, Hardy, and others have given us a clue to possible explanations of the various appearances seen both in the living and dead fixed and stained cells, and the introduction of the ribbon section cutting microtome into the domain of vegetable histology has enabled us to make the best use of the beautiful apochromatic object-glasses which we owe to the researches of the late Prof. Abbe.

It is unfortunate that, so far, very little progress has been made in the examination of the structure of the living cell. We may hope that, with the improved methods of illumination now available, combined with experimental investigation, it will be possible to make some progress in this direction. It is of the greatest importance that we should be able to satisfy ourselves to what extent the various appearances seen in the fixed and stained cell are due to the action of the reagents employed. In this respect a recent discovery by Köhler, which indicates the possibility of making use of the ultra-violet rays in such investigations, is of interest. Köhler (*Phys. Zeit.*, 1904) finds that if the ultra-violet rays from the electric spark between cadmium or magnesium terminals are separated out by means of quartz prisms, objects illuminated by them, when examined by means of lenses made of quartz, show differentiations of structure which otherwise require staining to make them visible. The chromatin of the nucleus and such substances as cuticle and cork are almost opaque to the ultra-violet rays, and can be made visible on a fluorescent screen or can be photographed. The resolving power of the microscope is doubled, and Lummer considers that the principle employed is the only one by which further progress in resolving power can be made. If the method is found by cytologists to be a workable one, it may open up an entirely new field of microscopic investigation by which the protoplasmic differentiation in living cells may be more clearly revealed.

Many attempts have been made to show that the cytoplasm possesses a definite morphological structure of its own, which is related to the various functions it performs, and that it is not a formless semi-viscid fluid in which various physical and chemical forces are at work, and upon which the various structures observed depend; in other words, that it possesses a morphological constitution as opposed to a merely chemical one.

Fromman and Heitzmann in 1875 described the structure of cytoplasm as consisting of fine threads or fibres in the form of a net with fluid between and forming a sponge-like structure. Flemming in 1882 described it as composed of two substances, one in the form of fibrils (filar substance) embedded in the other, a more or less homogeneous interfilar substance. In 1890 Altmans propounded his interesting hypothesis that all living sub-

stance is made up of minute granules or bioblasts, which are the real vital units or elementary organism, embedded in a homogeneous substance, the non-living matter. Cells are formed by a combination of these units of a lower order, and are therefore individuals or units of the second order.

At about the same time Butschli brought forward his celebrated hypothesis of the froth or alveolar structure of cytoplasm. This was based upon an extensive series of observations upon both living and dead cells as well as upon froths or foams made by mixing salts of various kinds with oil and then placing small particles of the oily mixtures so obtained in water.

Butschli compares the structure of cytoplasm to that of a fine froth, and considers that much of the granular, and network or fibrillar structure can be referred to the optical appearances presented by such a froth. That such structures are visible cannot be doubted by anyone who has examined these froths attentively with the microscope. But that all the fibrillar structures described by Fromman and Flemming, whose observations have often been confirmed since by competent cytologists, can be referred to a froth structure, cannot, I think, be accepted by anyone who has carefully examined plant cells.

From the fact that cytoplasm appears homogeneous under certain conditions, and that the foam structure can be so readily produced in it by various means, and further that, as Hardy has shown, the action of certain reagents upon colloids results in the separation of solid particles which become linked together to form a comparatively coarse, solid framework in the form of an open net which holds fluid in its meshes, it is probable that we shall find the foam-structure theory of protoplasm is not tenable. It seems far more in accordance with what we know that we should regard protoplasm as fundamentally a semi-fluid, homogeneous mass, in which, by its own activity, granules, vacuoles, fibrils, &c., can be produced as secondary structures; and that any special morphological structure which it may possess is beyond the limits of the present resolving powers of the microscope.

The Structure of the Nucleus.

From the recent observations of Gregoire and Wygaerts, Berghs, Allen, Mano, and others, it is difficult to arrive at any definite conclusions as to the structure of the nucleus, or as to the changes which take place in it leading to the production of the chromosomes. The resting nucleus seems to possess a very simple organisation. In the living condition it appears to consist merely of a homogeneous ground substance in which is contained a mass of chromatin granules which do not appear to have any particular shape, and one larger granule of a spherical shape, the nucleolus. Sometimes a network or foam structure is visible, but not always; but here, as in the cytoplasm, it is difficult to be certain of this. It may be that the chromatin is always in the form of an irregular network embedded in the colourless ground substance, and that the granular appearance is due to an optical effect similar to that observed in finely meshed oil-foams. According to Strasburger, Miss Sargant, Farmer and Moore, Mottier, and others, the nucleus contains an achromatic network—the linin—in which the chromatin granules are embedded. Mano, Moll, and Sypkens deny the existence of these two substances, and state that the network consists of chromatin only; while Gregoire and Wygaerts, Allen and Berghs, are inclined to the view that there is a fundamental basis of linin which is impregnated by chromatin ordinarily diffused through its whole substance, but capable of being collected into certain definite regions under certain conditions by which the granular appearance is produced. The evidence brought forward in many of the more recent investigations certainly goes to show that the chromatin is not in the form of such definite granules as was at one time supposed; that they are not so regular in size or outline; and that it is not easy to differentiate between the chromatin and achromatin contents of the nucleus. Staining reactions do not afford a sound clue to their differentiation, for, as Fischer and, more recently, Allen have shown, the differences in staining reactions of the different parts of the nucleus vary according to the strength of the stain, the time it is allowed to act, and the size or thickness of the granules or threads stained.

Strasburger has suggested that the chromosomes are formed by the fusion of gamosomes (chromatin granules) around gamo-centres into zygosomes (chromosomes), but the changes which take place are probably not so clearly defined as this. What seems clear from the facts we know is that the substance forming the homogeneous chromosomes—the chromatin or nuclein—becomes broken up in the reconstitution of the daughter-nuclei, by vacuolation or otherwise, into an irregular network which presents a granular appearance. In this all trace of the original individual chromosomes is in most cases lost, and at the same time one or more deeply staining bodies of a spherical, or nearly spherical shape—the nucleoli—appear in contact with it.

The Nucleolus and its Function.

The evidence is steadily accumulating that the nucleolus is intimately concerned in the formation of the chromosomes, although probably not exclusively concerned in this function. In most cases it appears to form a part of the chromatin network, being connected to it by threads, and generally gives similar reactions to the chromosomes. In some few cases it is described as completely separated from the network by a clear area which is visible both in the living and in the stained condition. The evidence that the nucleolus is concerned in chromosome formation may be summed up as follows: the nucleoli are closely connected or associated with the nuclear network; as the nuclear network becomes more deeply stained the nucleoli become smaller or lose their capacity for stains; at the time the chromosomes are being differentiated they are connected to the nucleoli by delicate threads; the chromosomes resemble nucleoli in their behaviour towards reagents and stains; during the period of sinapsis the nucleoli come into very close relations with the nuclear thread, and as the nucleus gradually passes out of the sinaptic stage the thread stains more deeply; in the reconstitution of the daughter-nuclei the chromosomes can be seen to fuse together into a more or less irregular mass, out of which the delicate nuclear network and the prominent nucleolus are evolved; in certain cases all the chromatin appears to be stored up in the nucleolus.

It has been suggested that the nucleolar substance is a product of excretion of the nucleolus, but there is very little evidence for this view. On the other hand it is very likely, as suggested by Mottier, that the nucleolus contains a store of nutritive material which can be used up for various purposes, both in the nucleus and in the cytoplasm. In some cells a portion of the nucleolar substance is thrown out into the cytoplasm during the division stages, and it is very probable that this may have some important connection with the metabolic activity of the cell at this period.

Division of the Nucleus in the Spore Mother-cells.

The divisions of the nucleus which lead immediately to the formation of the spores possess some features which are not found in ordinary vegetative mitosis, and which have an important bearing upon the facts of heredity. The first of these is known as the heterotype, the second as the homotype division. The essential features of the heterotypical division are as follows:—The chromatin net becomes gradually resolved into a more or less continuous spireme. This thread (or threads) contracts into an irregular mass around the nucleolus, a phenomenon which was first discovered by Moore, and to which he gave the name of "sinapsis." Some observers regard this contraction as caused by reagents; but since it has been observed in the living condition by Miss Sargant and others, it is probably a definite and normal stage in the division. It is concerned with some very pronounced changes which take place at this time in the nucleus. The nuclear thread becomes more prominent, stains more deeply and exhibits a double row of granules which gives it the appearance of a double thread. This has been variously interpreted by different investigators: Miss Sargant, Farmer and Moore, and many others consider that it is due to a longitudinal splitting of the thread; Dixon, Gregoire, Berghs, and Allen consider it as indicating a close approximation of separate loops of the

thread. Whichever of these explanations is the correct one, the doubling gradually disappears and the thread becomes distributed through the nuclear cavity and again appears single; it becomes shorter and thicker and once more becomes aggregated around the nucleolus. This may be, as Miss Sargant suggests, a second sinapsis. At this stage the chromosomes appear, but reduced to half the number of those which appeared in the previous divisions, so that they may be regarded as bivalent or double chromosomes. They become shorter and thicker, and gradually become grouped in the equatorial plane of the nucleus, where they become attached to the spindle fibres. Each chromosome now divides into two halves, which pass to the respective poles of the spindle, to form, without the intervention of a complete resting stage, the division figures of the daughter-nuclei.

The exact mode in which the division of the chromosomes into two halves takes place is the subject of much controversy. The studies of Weissman on the phenomena of heredity led him to the conclusion that the chromosomes consist of more than one complete ancestral germ-plasm, and that consequently these must be reduced in number in the sexual cells to escape the extraordinary complexity which would arise if the ancestral germ-plasms were doubled at each sexual fusion. As the longitudinal division of the chromosomes divides them into two equal halves it is obvious that this will not reduce the number of ancestral germ-plasms, and therefore Weissman predicted that a transverse division of the chromosomes would be found to take place by which the reduction would be brought about. This was soon discovered to be the case for many animal cells, the reducing division taking place during the formation of the sexual cells, but in plants this was not so easily determined. Belajeff, Dixon, Atkinson, and others maintained that a true reduction division took place in the cases examined by them; but the majority of observers, Miss Ethel Sargant, Strasburger, Farmer, Mottier, and many others, maintained that there was no transverse division, but that all the divisions were longitudinal. Recently, however, Farmer and Moore have re-investigated the whole sequence of events in both animals and plants, with the result that a true reduction division is found to occur in the heterotype stage. In many investigations which have recently appeared this transverse division is confirmed, but the exact details of the process are not yet agreed upon. Farmer and Moore state that the spireme thread first becomes longitudinally split, the two longitudinal halves then fuse again, and subsequently bivalent chromosome loops are formed which divide transversely in the middle, and so produce two monovalent chromosomes which pass to opposite poles of the spindle, as already described. Gregoire, on the other hand, states that the threads at the first sinapsis become approximated together and then fuse; the double thread thus produced breaks up into chromosomes, which are thus bivalent in a different sense from those of Farmer and Moore, the monovalent chromosomes being produced by a longitudinal splitting of the thread, which divides it into the two original halves which fused together.

Which of these two methods will ultimately be found to be the correct one remains to be seen, but Allen has recently published an account of the process as it occurs in *Lilium canadense*, in which he agrees substantially with Gregoire, and states definitely that the first appearance of the double nature of the thread is not due to a longitudinal splitting of a single thread, but to an approximation of two threads, which ultimately fuse together to form a single continuous thread in the nuclear cavity. This thread at a later stage undergoes a longitudinal splitting, possibly into those which formerly united; but this is not certain. The double thread then divides up into segments, the chromosomes, and in the subsequent series of events the longitudinal halves of these chromosomes become distributed to the opposite poles of the spindle. Each chromosome is thus seen to be bivalent; but whether each half of the chromosome is to be regarded as a monovalent chromosome is doubtful, as the fusion of the original threads was complete, and there is no means of deciding as to how far the subsequent longitudinal division of the completely fused thread separated it into its two original parts.

Sinapsis.

The term "sinapsis" was first given by Moore to that stage in the prophases of the nuclear division of the sexual cells in which the contraction of the nuclear thread around the nucleolus at one side of the cavity of the nucleus takes place. If this phenomenon is not a result of the action of the fixing reagents, then it indicates some striking change in the metabolic activity of the nucleus. This activity is seen in the increased staining capacity of the chromatin thread and in the changes which take place in the nucleolus, by which it becomes very irregular in shape and closely connected by threads to the chromatin network. In many cases the nucleolar substance appears as if being drawn out into the threadwork, and the nucleolus appears as if some active change were taking place in it.

It is very difficult to escape the conclusion that we are here dealing with a series of changes in the chromatin thread which are intimately bound up with the activity of the nucleolus, and it is probable that the increased stainability of the chromatin is due to an actual transference of a portion of the nucleolar substance into the thread.

Experimental Observations on the Activities of the Nucleus.

So far as I know no experimental investigations into the causes which bring about the changes in the prophases of nuclear division have been made, but it is not difficult to imitate artificially some of the phenomena observed. Olive oil is shaken up in a mixture of methylated spirit and water of such a strength as will allow the oil globules to float. A shallow Petrie dish, three or four inches in diameter, is then taken; the mixture of oil and dilute methylated spirit is well shaken until the oil is broken up into very fine globules, and the mixture is at once poured gently into it. The appearance of the mixture is that of a homogeneous mass of small oil globules distributed through the solution, and can be compared to the granular appearance of a nucleus in a resting stage. The spirit at once begins to evaporate, and currents are at once set up in the solution in such a way that the globules of oil gradually become restricted to certain areas only, and a coarse granular network is formed somewhat like the early stages in the aggregation of the chromatin granules into a spireme in the nucleus. The network gradually becomes more and more clearly defined, and then, just as is the case in the nuclear network, it begins to show a double row of granules, which finally becomes very clear and distinct. The threads become shorter and thicker and break up into irregular lengths, which gradually mass themselves together into an irregular heap or heaps of fusing-oil globules either in the middle or at the periphery of the petrie dish. We have, in fact, a good imitation of the earlier stages in the prophases of division of the nucleus, and it seems not unlikely that the aggregation of oil globules in our petrie dish may afford some clue as to the possible means by which the aggregation is brought about in the nucleus.

I do not suggest that the complex phenomena which take place in nuclear division are to be explained as due simply to such phenomena as diffusion, surface tension, and the like, or any other physico-chemical processes. We must be very careful not to attempt to force merely physico-chemical explanations upon such phenomena as these. Without admitting the necessity of anything akin to a special vital force, we are compelled to admit that vital phenomena do not at present admit of a merely mechanical explanation. But it does seem to me possible that the metabolic activity of the nuclear material at this stage may be accompanied by phenomena referable in part to these agencies. If, for example, active metabolic activities are set up between the nucleus and cytoplasm through the nuclear membrane, as seems probable, it is quite conceivable that this would bring about diffusion currents which might be taken advantage of in producing the aggregation of the more solid parts of the nuclear substance into a more or less definite thread-like structure and its aggregation into chromosomes. In any case such possibilities must be taken into account in considering

the significance of such nuclear re-arrangements, and if any of them can be definitely explained in this way the final solution of the problem may be much simplified.

Validity of Cell Structure as seen in Fixed and Stained Preparations.

Our knowledge of the minute details of cell structure and nuclear differentiation depends upon the appearances presented by cells which have been fixed in various reagents and subsequently stained, and it is not an easy matter to determine in how far these are artificial and in how far they are actual structures existing in the living cell. The researches of Fischer, Hardy, Mann, and others have shown that on the precipitation of proteids by reagents structures are produced which were certainly not present originally, and which resemble those often observed in fixed cells. From a consideration of such facts it has been suggested that many of the details revealed in fixed cells, such as centrosomes and centrospheres, with their fibrillar radiations, are produced artificially and have no real existence. It is unfortunate that so little attention has been paid to the examination of living cells, for the structures which can be seen in them are, so far as they can be revealed by the microscope, always like those seen in fixed preparations.

Differentiation of Structure Visible in the Living Cell.

The amount of differentiation visible in the living cell in favourable objects is very considerable. Not only can chloroplasts, starch-grains, nucleus, leucoplasts, pyrenoids, &c., be clearly seen, but also a very considerable amount of detailed structure. Chromosomes have been seen in the living cell by many observers—Treub, Strasburger, Behrens, Zacharias, and others. The series of figures published by Strasburger of nuclear division in the staminal hairs of Tradescantia show the whole process of chromosome formation and separation into two daughter-groups, except the longitudinal division.

In the same object Demoor and de Wildeman have also been able to detect the spindle fibres and connecting fibres. These were not seen by Strasburger; and Zacharias, who has more recently made observations on staminal hairs, was also not able to detect them. Nevertheless Strasburger mentions that in some cases connecting threads were visible at a late stage in the division between the daughter-nuclei, and Treub also describes a similar phenomenon in some cases during the nuclear division in the ovules of an orchid.

In Spirogyra, Strasburger has given a full account of nuclear division in the living cell. Large species of this alga are very favourable objects for this work, and he has shown that in such species the spindle figure as well as the connecting fibres can be seen in the living cell. Wildeman has also seen and figured them; but Behrens states that spindle fibres and connecting threads are not visible in Spirogyra during life.

My own observations upon a large species of Spirogyra which I have had an opportunity of investigating entirely support the view that these structures are visible in the living condition.

The Structure of the Chloroplast.

In view of its extreme importance in the function of assimilation a knowledge of the structure of the chloroplast is important. Owing to its small size a satisfactory demonstration of its finer structure is very difficult. That it consists of a colourless ground substance, in which the chlorophyll is embedded, is clear; but how these two substances are united and the relations between them structurally are not known. Pringsheim concluded that the ground substance of the chloroplast is a sponge-like network with the oil-like solution of chlorophyll in its meshes.

Schmitz thought that the fine granular appearance of the chloroplast was due to a fine net-like structure in which the chlorophyll was diffused. Fromman also describes it as a green granular network. Schwartz, on the other hand, describes it as composed of a ground substance containing a number of green fibrillæ side by side, which are coloured green throughout, but show also an accumulation of the green colouring matter in the form of granules along these threads.

Meyer thought it was composed of a homogeneous ground substance with various-sized granules of the green substance embedded in it. To these granules he gave the name of "grana." Schimper stated that it was composed of a colourless stroma containing numerous vacuoles filled with the green semi-fluid chlorophyll, identical with the "grana" of Meyer.

Some observers consider that the chloroplast is surrounded by a distinct membrane; whilst others consider that the substance of the chloroplast is directly connected by colourless strands to the cytoplasm.

According to some observations which I have made recently, the chloroplast, when examined under high powers in the living condition, appears to be filled with a mass of green granules with a colourless substance between them. But in certain cases a distinct fibrillar arrangement of the chlorophyll is observed. This is very easily seen in the chloroplasts of Euglena, both in the living condition, and, more easily, when the cells are burst and the chlorophyll grains are extruded into the water. But it may be seen also in the chloroplasts of the higher plants when these are large enough to be examined easily. In these cases the green colouring matter appears granular when the chloroplast is in the epistrophe or shade position, fibrillar when it is in the apostrophe or intense light position. This difference in the appearance of the chlorophyll accompanies a difference in the shape of the chloroplast. As is well known, the chloroplast in the epistrophe position presents an oval or more or less circular form; in the apostrophe position a flattened and lenticular form. The fibrillar structure appears to be that of fine fibrils lying more or less parallel, but a closer examination shows that they are connected together here and there so as to give the impression of an elongate network. In the epistrophe condition the chlorophyll corpuscle appears greener than in the apostrophe condition. The granules are in fact so arranged and so numerous as to present a practically continuous surface of chlorophyll to the action of the light rays. The fibrillar arrangement, on the contrary, has numerous light spaces between the fibrils, so that less surface of chlorophyll is exposed to the rays of light. The difference in the amount of chlorophyll surface exposed to the light appears therefore to be bound up with the difference in the intensity of light which causes the different positions of epistrophe and apostrophe to be assumed by the chloroplast. Just as in diffuse light the chloroplasts themselves are more fully exposed to the light than in intense light, so in the individual chloroplast we appear to have such an arrangement of the chlorophyll that in diffuse light a larger surface of it is exposed to the light rays than in a more intense light. The interesting conclusion is therefore arrived at, that the chloroplast is able, not only by its position but also by its structure, to guard itself against the effects of a too intense light.

A careful examination of the chloroplast in the epistrophe position renders it probable that the granular appearance is not due to the existence of separate granules of chlorophyll. It resembles more nearly an optical effect, due to the superposition of alveoli upon one another, such as appears in fine oil-foams. By focusing carefully above and below the granules we get a distinct appearance as of a green alveolar network. If the chlorophyll corpuscle is extruded into water it begins to swell up and becomes vacuolar; the granules disappear and the chlorophyll then appears to be distinctly diffused through the ground substance of the chloroplast. I am therefore inclined to the view that the chlorophyll corpuscle consists of a ground substance in the form of a delicate alveolate structure, in which the chlorophyll is more or less uniformly diffused. The diameter of the threads of this network is greater in the epistrophe than in the apostrophe position, and this affords a means by which the chloroplast can accommodate itself to varying intensities of light.

The chloroplast must be regarded as performing at least two functions. It brings about the dissociation of CO_2 and it is a starch-forming organ. In the algæ and some other plants these two functions appear to be differentiated, and starch is formed directly by the pyrenoid. How far these two functions are independent in the ordinary chloro-

plast is not known; but that starch can be formed, independently of chlorophyll, in the leucoplasts and in the ordinary chloroplasts directly from sugar and other organic solutions in the dark seems to indicate that the two are not necessarily connected.

The colourless stroma of the chloroplast gives a distinct and pronounced reaction for phosphorus when treated according to Macallum's method. It resembles, therefore, in this respect the nuclein constituent of the nucleus. What the exact significance of the presence of phosphorus in the chloroplast may be I do not know, but it is extremely interesting to find that in an organ in which a high degree of metabolic activity is always found a substance should be present which is akin to the highly organised nuclear constituents. It suggests an interesting comparison with those plants in which a special starch-forming organ, the pyrenoid, is differentiated.

The Centrosomes and Centrospheres.

A vast literature has grown up in connection with the structure and function of these bodies because of the special importance which has been attached to them as the originators of the process of nuclear division and of the formation of the spindle, and because of the important part which it is assumed they play in the phenomena of fertilisation.

Their very general occurrence in animal cells and their prominence in the reproductive processes led plant cytologists to predict that they would be found to occur also in plant cells. But their prediction has not been fulfilled. They are frequently found among the Thallophytes and Bryophytes, but in the higher plants the evidence is steadily accumulating against them, and such structures as have been described by Guignard and others are held to be based upon a misinterpretation of the facts observed.

Where the centrosome exists it consists of a deeply stained granule or group of granules surrounded by radiating fibres. In some cases, as in the Basidiomycetes, the centrosomes only become definitely visible as minute dots at the poles of the spindle, and are not visible until this is completely or nearly completely formed. In other cases, as in Dictyota (Mottier), Ascomycetes (Harper), the centrosomes with their radiations are clearly visible at two opposite sides of the nucleus in the resting stage, and are in close contact with the nuclear membrane. In the Ascus, Harper has shown that the centrosome is in close contact, not only with the nuclear membrane, but also with the chromatin net, and it seems probable that there may be a connection between them. The spindle fibres are formed both in Dictyota and in the Ascus in the nuclear cavity before the nuclear wall breaks down. In the division of the daughter-nuclei the centrosome which is carried over with each daughter-nucleus appears to divide—but this is not certain—to give two new centrosomes for the formation of the new spindle figure.

Experiments on the Production of Artificial Asters.

There are two main views as to the nature of the spindle and astral fibres: (1) that they represent a definite morphological differentiation of the cytoplasm which possesses in itself the power of forming these fibres; (2) that they are formed out of the cytoplasm by some modification of its structure or arrangement of its parts, or by the precipitation or condensation of some of its constituents.

The aggregation of granules into radiating fibrils can be imitated artificially by allowing a drop of alcohol or turpentine to fall upon smoked glass. If the drop is allowed to fall from a good height, we get the artificial centrosomes with radiations first described by Henking; these are due mainly to the splash of the drop and its breaking-up into small particles which radiate outwards, carrying portions of the smoke film with them. If the drop is allowed to fall more gently, so that it does not splash, its first effect is to produce a clearly circumscribed circular ring, and then, by slowly spreading outwards, to produce an aggregation of the smoke particles into fibrils which more nearly represent the appearances produced in cytoplasm than do Henking's splashes.

By careful manipulation we can get in this way representations of the centrosome or centrosphere, or even the radiations around the nucleus. If the edge of the alcohol or turpentine be carefully examined under the microscope as it is slowly spreading outwards, a violent motion of the smoke particles will be observed as soon as the liquid comes into contact with them, and as the liquid passes on these particles settle down into definite continuous fibrils, which go on growing as the liquid continues to spread.

Fischer has described the formation of artificial asters by two methods: (1) If pith is injected with proteid and then fixed, asters are found around small particles of foreign matter in the proteid. (2) If a small granule of corrosive sublimate or a drop of osmic acid be brought into a proteid solution radiating striæ are formed in it by precipitation. He suggests that the centrosome is formed by the precipitation of albuminous substances in living cells by the excretion of nucleic acid from the nucleus, and that, as in (1), artificial radiations are formed around it by the action of the fixing reagents; or possibly by the fixative action of the nucleic acid itself. Or the centrosome itself may produce them, as in (2), by acting as the precipitating agent, just as corrosive sublimate or osmic acid. Mr. Jenkinson has recently described some interesting experiments on the artificial production of asters, and comes to the conclusion that osmotic pressure and surface tension are probably concerned in the formation of these structures in the living cell. The centrosome may be a body capable of withdrawing water from the cytoplasm, of swelling up and dissolving in the water so absorbed, and then giving off radial outgrowths which precipitate the proteids of the cell, and so form astral rays; or the centrosome may undergo decomposition, or may secrete a ferment which would have the same effect upon the cytoplasm.

The Blepharoplast.

The blepharoplast is a special organ associated with the formation of the cilia in motile spermatozoids and zoospores. It consists of a centrosome-like granule, often surrounded by radiations. It appears inside the cell in close relation to the nucleus, or sometimes at the periphery of the cell. In Polytoma the two cilia thus arise from a granule (blepharoplast) at the extremity of the cell. In Ædogonium the blepharoplast arises, according to Strasburger, in the plasma membrane. Strasburger considers them as kinoplasmic in nature, and thus brings them into relation with his other kinoplasmic structures, the centrosome and spindle.

Some authors consider that the blepharoplast is a true centrosome, or homologous with a centrosome. It has not, however, been conclusively shown that it at any period in its history performs the function of a centrosome, or that it is derived from one. Further, in many of these plants, if not all, there are no centrosomes at any stage in their life-history.

On the whole the evidence is distinctly against the view that the blepharoplast is genetically connected with the centrosome. It is more in accordance with the present state of our knowledge to consider the blepharoplasts as special structures which arise *de novo* in the cell for the special function of cilia formation.

The Coenocentrum and its Function.

In the oögonia of some fungi there appears at an early stage in the development of the oösphere a dense granular, deeply stainable substance, the function of which is unknown. It appears in the centre of the cell, and was first discovered in the oösphere of *Cystopus* (*Albugo*) *candida*. It is probably formed by an accumulation of stainable granules or microsomes. It disappears soon after fertilisation takes place, and is therefore not a permanent organ of the cell. Shortly after its appearance one of the nuclei out of the large number irregularly scattered through the oögonium comes into contact with it, and gradually becomes more or less embedded in it. All the other nuclei pass to the periplasm, leaving this single nucleus as the nucleus of the ovum. The fertilising tube which contains the male nucleus also grows towards it, and comes close to it to discharge the male nucleus upon it. This indicates that it may exert in some way or other an attraction, first upon the female nucleus, and secondly

upon the fertilising tube, thus helping to bring the sexual nuclei together. Stevens suggests that it may be of the nature of a dynamic centre, and he gave it the name *coenocentrum*. It may be nutritive in function, and may exert a chemotactic stimulus upon the sexual nuclei.

It does not appear to be actually concerned in the fusion of the sexual nuclei. In *Peronospora parasitica*, for example, it completely disappears before the fusion of the nuclei takes place. So far all the views as to its function are purely hypothetical. It may be a mere coincidence that it should become associated with the sexual nuclei at the time they come together in the oösphere. Its function may be totally unconnected with these. From the fact that it stains so deeply in nuclear stains, the substance of which it is composed may be of the nature of nuclein, and it is possible that it may be due to a substance secreted by the nuclei of the oögonium for some special purpose connected with the maturation of the oöspore. It is possible that it may have something to do with the formation of oil, which appears in such abundance in the ripe oöspores. It begins to disappear just at the time the oil begins to form.

It seems more likely that the function of the cœnocentrum is connected with those metabolic activities of the zygote, which must at this stage in its development be very considerable, than with the exertion of an attractive influence upon the sexual nuclei. It is difficult to see how such a selective chemotactic stimulus could be exerted as to act upon one nucleus only out of the large number in the oögonium. But the evidence before us does not admit of any definite solution of the problem at present. The subject demands further investigation of such a kind that a comparative study of the formation and disappearance of the cœnocentrum, the formation of the oil reserves, and the changes in the nuclei, should be carried on side by side.

The Nuclei of the Lower Plants.

The presence of nuclei in the algæ and fungi had already been recorded by Nägeli and many other observers shortly after the discovery of the nucleus by Robert Brown, but it is doubtful whether all the structures described as nuclei by these early observers were really so. It is only in comparatively recent times that it has been possible to determine with any degree of certainty that the minute deeply stainable bodies described more especially by Schmitz (1879) could be regarded as nuclei. This determination was easily made for many of the algæ, especially by the researches of Strasburger, who described both the structure and mode of division. But among the fungi the structure and mode of division of the nuclei were practically unknown twenty years ago, and we have the opinion expressed by De Bary in 1887 that the satisfactory discrimination of true nuclei from other small bodies contained in the protoplasm can only be obtained after renewed investigation.

Previous to 1887 cases of karyokinetic division in fungi had been described by Sadebeck (1883), Strasburger (1884), Fisch (1885), and Eidam (1887). Hartog (1889) described a process akin to karyokinesis in the Saprolegnieæ, and at the end of that year a true process of karyokinesis was shown to occur in Peronospora. Since that time our knowledge of the process of nuclear division in the fungi has been largely extended, and the phenomenon has now been found to be of general occurrence in the group, and many of the forms are unusually favourable objects for the study of the process.

The only groups of plants in which true nuclei have not been found are, so far as I know, the bacteria, Cyanophyceæ, and the yeast fungi. In the yeast plant there is a large homogeneous spherical body which gives the reactions of chromatin similar to the chromatin of true nuclei. With this is associated a prominent vacuole which contains a more or less amorphous substance of a chromatin nature. The two appear to be very closely related and undergo division simultaneously.

The Cell Structure of the Cyanophyceae.

It is easy to demonstrate in the living cell of the Cyanophyceæ that the contents are differentiated into two distinct regions: (1) an outer layer containing the colouring matter; and (2) a central colourless portion which is known as the central body. The central body is considered by many investigators to be a true nucleus. It contains a deeply staining granular substance which to some extent resists the action of digestive fluids, and is therefore similar to the chromatin in the nuclei of the higher plants. In 1887 Scott was able to demonstrate a reticulate structure in this body, and also saw some indications during its division of a process akin to karyokinesis. Zacharias also in the same year, largely on micro-chemical grounds, concluded that it was a nucleus. The problem has been the subject of investigation by numerous observers since that date with very varying results. These results may be shortly summarised as follows:—The central body is not a nucleus (Macallum, Fischer, Massart, Chodat). It is a nucleus of a simple or rudimentary type (Hieronymus, Nadson, Butschli). It is a true nucleus similar to that found in the higher plants, and forms both chromosomes and spindle (Hegler, Kohl, Olive, Phillips).

The facts of the structure of this body, so far as I have been able to ascertain them by the examination of the cell both in the living and fixed conditions, are that it possesses a vacuolate structure, associated with granules which stain deeply in nuclear stains, resist the action of digestive fluids, give a strong reaction for phosphorus and masked iron, and, further, according to the recent researches of Macallum, do not contain potassium. These qualities are characteristic of nuclein, and there can be, I think, no reasonable doubt that these granules are comparable to the chromatin of a true nucleus.

From a consideration of the facts we at present know concerning the central body we cannot, I think, escape the conclusion that it is of the nature of a nucleus, but one of a simple or rudimentary type. It is not sharply delimited from the surrounding cytoplasm, although it sometimes appears as a vacuolar cavity in the centre of the cell, with a vacuolar membrane around it. It seems to me that we might very well regard it simply as a specialised region of the cytoplasm which possesses a pronounced vacuolation associated with granules of chromatin or with a chromatin network.

The Function of the Nucleus of the Cyanophyceae.

The nucleus of the Cyanophyceæ is very large, much larger proportionally than the nuclei of the higher algæ. It gives also a proportionally stronger reaction for phosphorus. Some observers have considered the large size and prominence of the central body as an argument against its nuclear nature. In the algæ the nuclei are much smaller in proportion to the cell, and in many forms are very difficult to make out. On the other hand the pyrenoids which are present in the cells of Algæ stain more deeply in the nuclear stains, and give a much stronger reaction for phosphorus than the nuclei. In *Prassiola parietina* the pyrenoid is in the centre of the cell, and both in the living condition and in stained preparations is much more prominent than the slightly stained nucleus on one side of it. So, also, in Zygnema there are two star-shaped chromatophores, each with a large pyrenoid in the middle, and between them a small very inconspicuous nucleus.

My view is that the large size of the central body in the Cyanophyceæ may be connected with the development of the chlorophyll assimilation; that it may be held to function both as a pyrenoid as well as a nucleus, and that this receives support from what is observed in the coloured bacteria, in which the cytoplasm contains a more abundant supply of chromatin granules than do the colourless bacteria.

Structure of the Bacterial Cell.

Owing to the small size of the bacterial cells it is very difficult to arrive at a correct interpretation of the structures observed. The examination of the larger forms, such as the various species of Beggiatoa, Chromatium, *Bacillus anthracis, Bacillus subtilis,* &c., has, however, revealed a certain differentiation, which enables us to come to some conclusions as to their actual structure. Ernst has shown that the contents of these cells are not homogeneous, as was formerly thought to be the case, but show a differentiation into a less stainable substance, and embedded in it one or more deeply stained granules.

Butschli has shown that the central portion of the contents of the cell exhibit a foam structure in which granules of a chromatin nature are embedded: this is surrounded by a thin layer of a less deeply stained substance, which sometimes accumulates more prominently at the ends of the cell. The central, more deeply stained, froth-like structure with its granules is the nucleus; the delicate peripheral layer is the cytoplasm. From a recent examination which I have made of *Beggiatoa alba, Beggiatoa roseo-persicina, Bacillus subtilis,* and other smaller species, I cannot agree with Butschli that there is a differentiation into a central body or nucleus, and peripheral cytoplasm. In the various species of Beggiatoa and Spirilla which I have examined the cell contents exhibit a reticulate or foam structure of the cytoplasm in which one or more deeply stained granules may be embedded. As these granules stain deeply in nuclear stains, and also give a reaction for phosphorus, they are probably similar to chromatin. They are distributed throughout the whole cell, and are not specially confined to one place.

We must conclude that the bacteria do not contain anything which can be individualised as a nucleus, but that the nuclein constituent of the cell when present is contained in granules distributed throughout the cytoplasm.

The Evolution of the Nucleus.

All plant nuclei, from the algæ and fungi upwards, present a striking similarity both in structure and mode of division. The same appears to be true of the animal kingdom, from the protozoa upwards. But among the protozoa on the animal side, and the yeast fungi, bacteria, and Cyanophyceæ on the plant side, there is a kind of border kingdom in which occur structures which appear to represent the nuclei of the higher organisms, but are so different from them in many respects that it is very difficult to say whether they should be regarded as nuclei or not. As we have already seen, the central body of the Cyanophyceæ and the chromatin granules of the yeast plant and bacteria may represent simple or rudimentary forms of nuclei. It is, therefore, possible that we may obtain from them a clue or indication of some kind as to the origin of the nucleus and the process of its evolution.

It is among the protozoa that we find the greatest variation both in form and structure of these rudimentary nuclei. All the various parts of the nuclei of the higher animals can be recognised in them, but, as Calkins points out, are rarely present in one and the same nucleus. From a consideration of the various types Calkins considers that the most primitive nucleus is probably a single mass of chromatin without membrane or reticulum. By the division of this into granules, their association into lines forming primitive chromosomes, the development of a linin network, and the formation of a definite nuclear membrane was gradually brought about the development of the typical nucleus.

In the three groups of plants the Cyanophyceæ, bacteria, and yeast fungi it is not possible to recognise all the various parts of typical nuclei as in the protozoa. In none of them do we find a nuclear membrane, nucleolus, chromosomes, or spindle figure, or centrosome. We have nothing very tangible, therefore, to compare with the typical nucleus of the higher plants, and it is no doubt very largely due to this that we have so many contradictory accounts of the nuclear structures in these forms.

At the same time the nuclei of the higher plants pass through stages in their division which more nearly approach in their structure the simple forms with which we are now concerned. Thus the nuclear membrane and nucleolus disappear, and the chromatin network becomes condensed into a number of homogeneous rods or granules, the chromosomes, which lie free in the cytoplasm. There seems to be no reason why we should not consider the simpler chromatin structures in the lower plants in the light of these ontogenetic changes, as we may term them, of typical nuclei, in order to obtain some indication of the origin and phylogenetic development of the nucleus.

We may take the colourless Beggiatoa as a starting-point; not that this form is the lowest, but because its structure is, on account of its size, more easily examined, and because it is connected possibly with the Cyanophyceæ on the one hand and with the ordinary bacteria on the other. From a careful examination and comparison of its structure with that of other low forms we obtain the following diagram, showing their possible relationships as indicated by their cytological structure:—

?

Beggiatoa alba.
(Chromatin granules may or may not be present.)

Beggiatoa roseo-persicina, Chromatium okenii, &c.
Many chromatin granules often condensed in the centre of the cell. Cytoplasm coloured.

Cyanophyceae.
Central body with chromatin granules surrounded by a peripheral coloured protoplasm.

?

Algæ.

Larger Spirilla with colourless cytoplasm. (Few small chromatin granules).

Forms like *Cholera vibrio, B. lineola, B. anthracis, Typhus bacillus,* &c. Colourless. (One or two chromatin granules.)

Yeast Fungi.
With one or two chromatin granules associated with a nutritive vacuole.

Fungi.

In the simplest case the cell of Beggiatoa contains only cytoplasm without, so far as I can see by careful examination with the highest powers available, any differentiation of chromatin grains or structures of a like nature. Neither do I think that we can regard the protoplast as representing a nucleus. As Fischer points out, the idea that the protoplast of the bacteria stains like a nucleus is not correct, and, as I have been able to show, it certainly does not give a phosphorus reaction like a nucleus. It is, in fact, a simple undifferentiated mass of cytoplasm, either homogeneous or at times exhibiting a foam structure. In this cytoplasm a few granules of chromatin may become differentiated, and this is the first indication of the separation of nuclear substance. Whether there are any species of Beggiatoa or other bacteria which are permanently without nuclear granules I do not know, and it will be very difficult to prove it: but the fact that under certain conditions these cells exist without them seems to point to the conclusion that this may be the primary cell structure, as has been surmised by Haeckel and others.

At an early stage in the evolutionary history of the protoplasm, before a typical nucleus was evolved, we appear to have had the development of colouring matter for the function of assimilation, and a bifurcation into the two distinct lines of descent of the fungi and the algæ. This appears to have been accompanied by two distinct lines of nuclear evolution leading respectively to the development of the central body of the Cyanophyceæ and the nuclear apparatus of the yeast plant. The possible lines of development of the nucleus up to the yeast fungi on the one side and to the Cyanophyceæ on the other are clearly indicated in the diagram; but between the yeast fungi and the true fungi, and between the Cyanophyceæ and the Algæ, there are gaps which we cannot bridge at present. It is possible that the evolution of the typical nucleus may have been brought about in the fungi by the more definite association of the nuclear vacuole with the homogeneous nuclear body, possibly accompanied by a vacuolation of the latter, or that the nuclear body itself

may have become the nucleus direct by a process of vacuolation and differentiation within itself.

In the case of the Cyanophyceæ I have already shown that the central body is a vacuolar structure associated with granules of chromatin, and that sometimes this vacuolation becomes so pronounced in resting cells that we get an appearance as of a limiting membrane between it and the cytoplasm. The granules run together and become associated in such a way as to simulate the spireme thread of an ordinary nucleus. Further, we have in some Cyanophyceæ a differentiation of a nuclein-like substance in the form of the red granules of Butschli at the periphery of the central body, which may be an early stage in the separation of a portion of its substance to perform the special functions of the pyrenoid. The complete separation of this into a definite pyrenoid and the formation around the remainder of a nuclear membrane would give us a differentiation comparable to some extent to what we find in *Euglena viridis,* where we have a reticulate nucleus which divides by a rudimentary process of karyokinesis, in which, so far as we know, there is no definite formation of chromosomes and no longitudinal splitting.

As to when or how the higher differentiation of the nucleus, with its chromosomes, longitudinal division, and spindle figure, arose we do not know. Possibly a careful investigation of the lower forms of the fungi and algæ and such organisms as Euglena, and especially the protozoa, may throw light upon this difficult problem.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

SIR DONALD CURRIE has promised to give 20,000*l.* to the equipment fund of Queen's College, Belfast, provided an equal sum is raised from other sources. It is understood that a considerable portion of this amount has already been promised.

MR. E. TOWYN JONES, demonstrator in chemistry at University College, Bangor, has been appointed assistant lecturer and senior demonstrator in the department of chemistry and physics of the Pharmaceutical Society of Great Britain.

IT is announced that Mr. Bazil McCrea has given 6000*l.* to found a chair of experimental physics in Magee College, Londonderry, and to provide two scholarships in connection therewith. The gift is conditional upon funds being provided by subscription within six weeks for the erection of a suitable physical laboratory.

WE have received the year-book of the Michigan School of Mines for 1904–5, and an album of views showing the facilities for instruction afforded by the immediate surroundings of the college. Established in 1885, the college is situated at Houghton, in the heart of the great copper mining region of Lake Superior, with the deepest shafts in the world and the most powerful machinery ever employed in mining. The students also have access to the docks, railways, dressing plants, and smelting works. The special facilities for practical training largely account for the success which the institution has attained. There are at the present time 223 students, their average age being 22½ years.

THE metropolitan medical schools will re-open for the winter session on October 2 and October 3, and in many of them inaugural addresses will be delivered. At University College the address will be given on October 2, at 4 p.m., by Prof. Kenwood on "Preventive Medicine: Past and Present"; at King's College on October 3, at 3 p.m., by Prof. Clifford Allbutt, F.R.S., on "Medical Education in London," and an opening lecture on October 4, at 4 p.m., by Prof. Dendy on "The Study of Zoology"; at Charing Cross Hospital on October 2, at 4 p.m., by Sir James Crichton-Browne, F.R.S.; at St. George's Hospital on October 2, at 3 p.m., by Mr. Brudenell Carter; at the Middlesex Hospital on October 2, at 3 p.m., by Dr. R. A. Young; at St. Mary's Hospital on October 2, at 3.30 p.m., by Dr. Wilfred Harris; at the London (Royal Free Hospital) School of Medicine for Women on October 2, at 4 p.m., by Mrs. Bryant, D.Sc.; at the London School of Tropical Medicine on October 10, at 4 p.m., by Dr. Nuttall; at the School of Pharmacy, Pharmaceutical Society, on October 2, at 3 p.m., by Sir Boverton Redwood; and at the Royal Veterinary College on October 2, at 4 p.m., by Mr. W. Hunter. At Guy's, the London, St. Thomas's, and Westminster hospitals there will be no inaugural addresses, but at the first named Prof. Osler, F.R.S., will open the session of the Pupils' Physical Society with an address on "Some Reminiscences of Sir Thomas Browne" on October 12, at 8 p.m.

THE second volume of the report of the Commissioner of Education for the year 1903 has now been received from Washington. The bulky volume of some 1300 pages is largely concerned with statistics, full data being provided concerning every grade of educational institution. Dealing with the income of colleges and universities, the report shows that in the United States the State and municipal aid to higher education during 1903 amounted to 1,591,000*l.*, of which 1,034,000*l.* was granted for current expenses and 557,000*l.* for buildings and other special purposes. The total value of all gifts and bequests reported during the year to the commissioner by universities and colleges amounted to 2,950,000*l.* The three institutions receiving the largest sums for the year under consideration were:—University of Chicago, 487,500*l.*; Harvard University, 351,300*l.*; and Barnard College, 225,600*l.* The universities and colleges in the States of the North Atlantic and North Central divisions continue to receive the greater portion of benefactions, more than 90 per cent. of the total amount being reported by them in 1903. Dr. John Eaton, who was formerly United States Commissioner of Education, contributes biographical sketches of American educational benefactors and of American citizens whose lives were devoted to educational work, and this brightly written section of the volume affords another indication of the way in which the men of wealth in the United States are encouraged by those in authority to interest themselves in educational progress.

THE polytechnics and technical institutes of London will open shortly for the winter session, and the issue of new calendars and syllabuses has begun already. The session of Birkbeck College will commence, we learn from its new year-book, on October 2, when Sir Edward Fry will deliver the inaugural address. Afterwards the class-rooms and laboratories will be opened for inspection, and an exhibition of work will be held in the school of art. The work of Birkbeck College is conducted in close relation with the University of London, courses of study for examinations of the university being provided under recognised teachers of the university. In addition to evening classes in almost every department of learning, there are day courses of work which give instruction in practical and theoretical science, in classics, in modern languages, in commercial subjects, and in English literature. The moderate fees will enable students of limited means to take advantage of the lectures and laboratory work which have been arranged at this central institution. The syllabus of classes at the Sir John Cass Technical Institute has also been received, and supplies gratifying evidence of the excellent provision of scientific and technical instruction which is available in Aldgate. It is satisfactory to find that in addition to systematic courses of lectures, special attention is given to laboratory work with a view to bring home to students the general and fundamental principles of science in association with the work and products with which they are more immediately concerned in their daily life.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, July 20.—"A New Formation of Diamond." By Sir William **Crookes,** F.R.S.

Assuming the following data for carbon—boiling point 3870° ab., melting point 4400°, critical temperature 5800°, critical pressure 2320 ats.—the Rankine or Van der Waals formula calculated from the boiling point and critical data gives for a temperature of 4400° ab. a pressure of 16.6 ats. as the melting-point pressure.

Making similar estimates for other temperatures, it appears that above a temperature of 5800° ab. no amount of pressure will cause carbon vapour to assume liquid form, whilst at 4400° ab. a pressure of above 17 atmo-

spheres would suffice to liquefy some of it. Between these extremes the curve of vapour pressure is assumed to be logarithmic.

In their researches on the gases from fired gunpowder and cordite, Sir Frederick Abel and Sir Andrew Noble obtained in closed steel cylinders pressures as great as 95 tons to the square inch, and temperatures as high as 4000° C. According to a paper recently communicated to the Royal Society, Sir Andrew Noble, exploding cordite in closed vessels, has obtained a pressure of 8000 atmospheres, or 50 tons per square inch, with a temperature reaching in all probability 5400° ab.

By the kindness of Sir Andrew Noble, the author has been enabled to work upon some of the residues obtained in closed vessels after explosions, and he has submitted them to the same treatment that Moissan's granulated iron had gone through. After several weeks he removed the amorphous carbon, the graphite, the silica, and other constituents of the ash of cordite, and obtained a residue among which, under the microscope, crystalline particles could be distinguished. Some of these particles, from their crystalline appearance and double refraction, were silicon carbide; others were probably diamonds. The whole residue was dried and fused at a good red heat in an excess of potassium bifluoride, to which was added during fusion 5 per cent. of nitre. The residue, after thorough washing and then heating in fuming sulphuric acid, was washed, dried, and the largest crystalline particles picked out and mounted.

From the treatment these crystals have undergone, chemists will agree that diamonds only could stand such an ordeal; on submitting them to skilled crystallographic authorities the author's opinion is confirmed.

PARIS.

Aacdemy of Sciences, September 11.—M. Troost in the chair.—Remarks on the present condition of solar researches and on the means of improving them: H. **Deslandres.** The author proposed in 1893 that automatic apparatus should be established at suitable spots capable of registering the surface of the sun and the successive layers of its atmosphere. As this has so far not been realisable, on account of the expense, suggestions are now put forward for the correlation of the work of the observers actually engaged in solar research, and these suggestions will be submitted to the International Union at the meeting to be held at Oxford.—On a differential equation of the fourth order: Gaston **Darboux.**—On some properties of the α rays of radium: Henri **Becquerel.** The author showed, two years ago, that the bundle of α rays behaves as homogeneous in the magnetic field, and also that the trajectory of the particles in a plane normal to the field, instead of being a circle, is a curve the radius of curvature of which goes on increasing with the length of the trajectory. The recent work of Bragg and Kleeman and of Rutherford is discussed, especially the hypothesis of the slowing down of the particles used by the latter to explain the experimental results obtained when a series of aluminium screens is interposed in the path of the rays. The author has repeated his original experiments with the addition of aluminium screens, and the results confirm his views. On this account M. Becquerel thinks that the hypothesis of Rutherford regarding the loss of velocity of the particles must be rejected.—On the total eclipse of the sun of August 30: G. **Rayet.** An account of the results obtained by the expedition from the Observatory of Bordeaux at Burgos, Spain. The weather was bad, and interfered with the work of several of the observers. In spite of this, however, two good images of the corona were obtained by M. Courty with the photographic equatorial. M. Esclangon was able to follow the variations in the polarisation during the eclipse.—On the method of using captive and pilot balloons at sea: **Prince of Monaco.** Details are given of the mode of launching the balloons and of maintaining them at heights fixed on beforehand. The observations were carried out in the Mediterranean and in the trade winds region of the Atlantic, the maximum height attained being 14,000 metres.—On the eclipse of August 30, and on the polarisation of the solar corona: Georges **Meslin.** The proportion of polarised light is sensibly the same in the polar and equatorial regions—it is about 50 per cent. Elliptical polarisation could not be detected.—On two particular cyclic systems: A. **Demoulin.**—On the generalisation of algebraical continued fractions: M. **Auric.**—On Monge's problem: M. **Zervos.**—On the physical units of albuminoid material and on the part played by lime in its coagulation: G. **Malfitano.** By repeated coagulation it was found to be impossible to free the albumin entirely from inorganic substances, and the author regards the precipitate as aggregates of molecules, associated with electrolytes. It is probable that the mechanism of peptonisation consists essentially in a change in the nature of the salts which are associated with these aggregates.—The influence of the eclipse of August 30 on some plants: Ed. **Bureau.** *Acacia dealbata* proved to be the most sensitive to light, and during the eclipse executed the nocturnal movements, whilst other species of "sleeping" plants were unaffected.—On the evolution of the liver: Camille **Spiess.**—The vibration of the eyelids in renal affections: G. **Ullmann.** This has proved a valuable sign in affections of the kidney, and is present at the earliest stages.—The direct solution of the silicates from arable earth and the experiments of Daubrée: L. **Cayeux.** The author controverts the views of Delage and Lagatu on this subject, and holds that the experiments of Daubrée have been wrongly interpreted by these authors.—The waterspout of August 28 at Saint-Maur and at Champigny (Seine): Th. **Moureaux.**—On the meteorological observations made at Constantine during the eclipse of August 30: Henry **de la Vaulx** and Joseph **Jaubert.**—On the phenomenon of moving shadows: Lucien **Libert.**—An earthquake shock registered at Grenoble, September 8: MM. **Kilian** and **Paulin.**

NEW SOUTH WALES.

Linnean Society, June 28.—Mr. T. Steel, president, in the chair.—Description of a new species of Actinotus from eastern Australia: R. T. **Baker.**—Revision of the Australian Curculionidæ belonging to the subfamily Cryptorhynchides, part vii.: A. M. **Lea.**—Descriptions of five new species of Cicindela from tropical Australia: T. THURSDAY, SEPTEMBER 28, 1905.

A TREATISE ON PLAGUE.

A Treatise on Plague. By Dr. W. J. Simpson. Pp. xxiv+466. (Cambridge: University Press, 1905.) Price 16*s.* net.

THIS volume deals with the historical, epidemiological, clinical, therapeutic, and preventive aspects of plague, and it marks a distinct and important addition to what has hitherto been written about the subject. It gives a careful and well arranged summary of many writings, ancient and modern, which deal with oriental plague. Many of the ancient writers, some interesting and basing their statements on carefully observed facts, others less interesting and largely fanciful, are here succinctly placed side by side, and the advances or the reverse evolved out of them for subsequent generations are described in chronological order. What the reader of this volume will at once perceive as a marked difference from other works on plague is the recognition of the important bearing of the discovery of the *Bacillus pestis* as the real cause of the disease, and its influence on our knowledge of the manner of spread of the disease and its prevention. In these respects Dr. Simpson, as an epidemiologist of recognised standing, and by his practical knowledge of the bacteriological aspect, is in a distinctly more favourable position than previous writers on plague.

The subject-matter is dealt with in four parts in twenty-one chapters. Part i. gives an account of the history and distribution of plague from the earliest recorded times down to the end of the nineteenth century—chapter i.—and comprises accounts of plague in Syria, Arabia, Mesopotamia and Persia, Egypt, Lybia, Constantinople, and the west of Europe, including Germany, Italy, and England during the sixteenth and seventeenth centuries. The references to the various writers are everywhere carefully given, and include writers like Procopias of Cesarea, Evagrius of Antioch, Gregory Bishop of Tours, Paulus Diaconus, A. v. Kremer, Nicophorus Gregoras, Guy de Chauliac, Ed. Maunde Thompson, Patrick Russell, and Dr. C. Creighton's "History of Epidemics in Britain." This chapter i. contains in thirty-nine pages a review of a vast amount of interesting literature not readily accessible to the ordinary student.

Chapter ii. deals separately with plague in India, which at the present time is of special interest to English readers. Before the seventeenth century, since when more or less accurate records are available, "the history of plague in India is veiled in obscurity. That plague did prevail in India in or before the eleventh or twelfth century is certain, for in some of the Puranas which are at least 800 years old there are references to the disease and instructions to the Hindus as to the precautions to be taken in the event of its appearance. One of these is that whenever a mortality among the rats of a house is observed the inhabitants are to leave" (p. 40). There is evidence of extensive pestilences in India in the fourteenth, fifteenth, and sixteenth centuries. At the beginning of the seventeenth century plague broke out in the Punjab and spread over different parts of India, the outbreaks in Surat, Bombay, and Bijapur towards the last part of the seventeenth century having been of a particularly virulent character.

"Nothing more is heard of the disease (p. 46) on the western side of India until 1836, when the Pali plague broke out in Marwar in Rajputana and lasted until 1838 (Dr. Forbes)," and according to the same authority this epidemic was brought from Asia Minor and Mesopotamia. Next comes the consideration of Garwhal and Kumaon (both at the southern slopes of the Himalayas), which are held by all authorities to be an endemic centre; "fortunately this centre is comparatively an inactive one as regards its powers of diffusion." Simpson, therefore, does not countenance (see also later) the somewhat sensational suggestion by Hankin that the epidemic in Bombay in 1896 and since was due to importation by fakeers from Garwhal. Chapter iii. deals in an exhaustive manner with the present pandemic, which is traced from Yunnan by the trade routes into different parts of China, and finally, in 1894, into Canton and Hong Kong. The outbreak and course of the epidemic into these two places are described from personal inquiries, as also the manner and extent to which these localities became centres of distribution of the plague to Bombay in 1896. The course and nature of the epidemic in Bombay Presidency, its extension into other presidencies and other countries, are illustrated by carefully executed maps.

Part ii. deals with the epidemiology of plague. Having briefly discussed the discovery of the *Bacillus pestis* by Yersin and Kitasato as the real cause of the disease, the author gives an account of the morphological and cultural characters of the microbe, of its vitality under various adverse conditions (heat, cold, drying on various substances) as asserted by various observers, and finally of its general effect and its pathogenicity after inoculation into rodents (chapter iv.).

In chapter v. the relationship of epizootics to plague is fully described. That rats and mice are susceptible to natural infection has been observed and mentioned by many writers, ancient and modern (Book of Samuel, vi., Bhajawata Purana, Nicophorus Gregoras, Lodge, Forbes, and many others). Dr. Hunter, of Hong Kong, and the author himself have published charts (reproduced) which give a comprehensive account of the parallelism of the human plague and rat mortality. While it is universally admitted as proved that in some epidemics the mortality of rats from plague coincides with the appearance of plague in the human being—either preceding it, synchronous with it, or following it—there is, on the other hand, good evidence (collected by the Indian Plague Commission, and discussed by Dr. Bruce Low in his Reports and Papers on bubonic plague, 1902) to show that epidemic outbreaks of plague in the human subject are not necessarily connected with plague in the rat. This is a point which ought not to be lightly passed over; it is unfortunate

Z

that in recent years it has been assumed by some epidemiologists that the essential factor in the appearance and spread of plague is the rat, whereas there exists good evidence that plague was introduced into, and broke out in, a locality in which neither antecedently nor concurrently any such epizootic was noticed—to mention, amongst others, the outbreak of plague in Oporto, and in Glasgow, 1900. No one questions the fact that plague has occurred on board ships in which plague rats had been found, nor that such rats on landing may carry and spread the disease amongst rats on shore, which themselves become a focus for plague amongst human beings; but it would be a serious omission on the part of sanitary officers were they to assume that this is the only, or even the chief, mode of importing the disease oversea or from one locality to another.

Chapter vi. deals with the different views regarding the etiology of pandemics and epidemics of plague, views which, with few exceptions, fall within periods antecedent to the discovery of the *Bacillus pestis*, and attributed a primary causality to influences which we now know to be accessory, though important, circumstances in the dissemination and spread of the disease, as, for instance, famine, scarcity, insanitary disposal of the dead, and others.

The known variations in diffusive powers of epidemics and the effect of seasonal influences are considered in chapter vii., and are illustrated by charts and diagrams, without, however, bringing us nearer to an explanation of the fact that seasonal influences play an important part, unless we accept as seriously meant the statement by Gottschlich, according to whom the seasonal periodicity of plague in Egypt is to be explained by the seasonal breeding period of the rat (p. 158).

The variation in virulence of plague epidemics is dealt with in chapter viii., and is illustrated by an account of various epidemics which have occurred in Astrakhan and Vetlianka, 1877–8; Avignon, 1348; Kathiawar, 1820; Pali, 1836; Marseilles, 1720; Egypt, 1834, and others. From these the author concludes that not only do epidemics amongst themselves show great variations in virulence, but that an at first mild epidemic is succeeded by one of great virulence in the same or subsequent years, and further that the various types may be running concurrently in the same locality and at the same time, *e.g.* at Kathiawar, Pali, Marseilles, Russia, and other places. The often observed fact that glandular swellings without fever may precede or follow plague prevalence is dwelt upon, without offering for it a satisfactory explanation, beyond the suggestion that variation of virulence may be due to change in virulence of the *Bacillus pestis* with change in the surrounding physical conditions, or to differences in susceptibility of those attacked, such as are brought about by scarcity and famine, poverty, insanitary dwellings, &c.

The conditions which foster endemicity and epidemicity are considered in chapter ix. The influence of the various at present existing endemic centres on dissemination of plague to exotic countries, the different conditions (poverty, misery, deficient food, overcrowding, insanitary dwellings) under which the various peoples have lived and still live, as, for instance, in the Himalayas, in Bombay, Canton, Hong Kong, Cape Town, and others, play an important part in predisposing to plague, "and it is in a population living under these social and local conditions that plague usually commits its greatest ravages" (p. 193).

The modes of dissemination from one locality into another and within an infected locality are described in chapters x. and xi. respectively. As to the first, illustrations are given that plague travels by the most frequented trade routes, that persons sick with or incubating plague carry infection, so also infected clothes and personal effects; that infection conveyed to a new centre (infected cargoes and infected rats) may affect rats before human beings; that owing to panic caused by plague breaking out in a given locality, open and secret flight of inhabitants are instrumental in the dissemination of the disease. In the dissemination of plague within an infected locality, importance is attached in the first place to the high infectivity of the pneumonic form of plague, as contrasted with simple bubonic plague, which is not directly infectious. Next stands the infectivity of the septicæmic form, in which the excretions contain the *Bacillus pestis*, wherefore clothes and rats play an important *rôle*. In the conveyance of plague from the rat to man, the part that insects—fleas, lice, bugs, ants—play is brought into prominence. In support of this theory, no valid experimental evidence is brought forward; what there is mentioned is more of the nature of strong belief. It is to be regretted that such prominence is given to this mode of dissemination, seeing that beyond the theoretical possibility, namely, that a blood-sucking insect of a plague-infected animal the blood of which, presumably, contains the *Bacillus pestis* might be the means of causing by its bite cutaneous inoculation of a new individual, including the human, there is not sufficient evidence that such has actually been observed either naturally or experimentally. All the direct evidence at present available is of a negative character. The numerous modes of conveyance of plague from man to man, from rat to rat, from rat to man and *vice versâ*, which have actually been observed both under natural as also under laboratory conditions (chapter xiii.) are quite sufficient to account for all the facts without ascribing to the flea any other than a very restricted and accidental *rôle*, if any.

Part iii. deals with plague in the individual. The morbid anatomy and pathology, including histology and distribution of the *B. pestis* in the different tissues, are described in chapter xii., as also the details of several autopsies of typical plague cases; whereas chapter xiii. gives an extensive description of the various channels by which an individual may receive the infection—the skin, and hence directly into the lymphatics; the skin, and hence directly into the bloodvessels; the mucous membranes, particularly of the fauces; the respiratory tract. The author accepts the three-fold grouping of plague infection made by the Indian Plague Commission

according to the duration of the incubation period in well ascertained cases.

The clinical symptoms, temperature charts, and some excellent photograms of the various forms of buboes in the living, the clinical history, treatment, and *post mortem* appearances of several specially selected cases are treated in a very readable manner in chapter xiv. While chapter xv. deals with the diagnosis and prognosis both from a clinical and bacteriological point, chapter xvi. is specially devoted to treatment, dealing with the methods used in the past, before the intimate nature of plague had been recognised, and in the present day, when Yersin's serum is extensively employed, giving statistical tables of the results of the use of this serum in Bombay, Karad, Karachi, Oporto, Natal, Hong Kong, and Brisbane, as also of Lustig's serum (p. 325), of that of Bondi and Terni, and of Kitasato.

This chapter concludes with a general account of prophylactic measures to be employed in an infected house, and of the injection of Haffkine's prophylactic into persons who have been exposed or are likely to be exposed to infection. Of the value of this prophylactic Dr. Simpson has no doubt, and recommends its immediate application.

Part iv. deals with measures for prevention and suppression of plague, those that were employed before the discovery of the *Bacillus pestis* (chapter xvii.), as also those at present in use (chapter xviii.). Amongst the former the measures used by the Venetians in 1348—in advance of all other countries and nations—deserve special notice, inasmuch as those measures were the first of a rational and organised nature, and practically are fundamental for all subsequent improvement and enlargements—lazaretto system of isolation, quarantine of men, merchandise, articles, and objects of various kinds. Amongst the existing measures are those agreed upon by the different Governments at the Venice Convention of 1897, and at the Paris Convention of 1903. Amongst the latter the importance of the destruction of rats is receiving a prominent place. While the use of fumigation of ships by means of the Clayton process, described in detail (pp. 359–365), unquestionably deserves the first place, undue prominence is given by the author to the Danysz bacillus (capable of causing acute fatal disease in rodents) as a means of rat destruction in localities other than ships. Owing to this prominence, the use of this microbe seems liable to lead to considerable disappointment; while the results of distributing with the food either cultures of this microbe or animals infected with it in the laboratory has been fairly satisfactory in some localities in destroying rats, in other localities it has been unsatisfactory. In some of the warehouses in the London Docks we distributed several dozens of cultures prepared by, and bought directly of, Dr. Danysz, as also a number of subcultures mixed with various foodstuffs, and a number of rodents (guinea-pigs, mice, and rats) dead after injection with virulent culture of the microbe; but while all these materials had been taken away by the rats of the warehouse, there was not a single dead rat found in consequence, nor was there afterwards any diminution of their number noticeable. Such unsatisfactory results have been observed also in other localities; it appears that the result depends not only on the virulence of the cultures (difficult to control), but also, and in a marked degree, on the species of rat. Moreover, recent observations show that even rats of the same species, but derived from different localities, are not susceptible to the Danysz virus in the same manner and to the same extent. The use, therefore, of the Danysz bacillus in one form or another can at best be considered only as a half-measure. It is precisely against half-measures, so frequently and so readily resorted to by indolent corporations and powers that be, that the author justly raises his voice in no uncertain manner (chapters xviii. and xix.), and we cannot help regretting that such prominence should have been given to a method falling far short of the drastic measures required to ensure the safe destruction of this dangerous vermin.

Chapter xx. is entirely devoted to a description of the nature, use, and results of preventive inoculation with Haffkine's plague prophylactic. The volume finishes with a reprint of the results of the International Sanitary Convention of Paris of 1903 *re* plague and cholera.

From the foregoing summary it will be seen that Dr. Simpson's "Treatise on Plague," dealing as it does with the disease from every aspect, is worthy to take a place in the foremost rank of the literature of the subject, and we have no doubt that it is destined to become an important and valuable aid to the student, the medical officer of health, to the epidemiologist, the sanitarian, and last, but not least, to the administrator.

E. Klein.

ASTRONOMICAL STEREOGRAMS.

Our Stellar Universe. A Road-Book to the Stars. By Thomas Edward Heath. Pp. 75. (London: King, Sell and Olding, Ltd., 1905.) Price 5*s.* net.

Our Stellar Universe. (Six Stereograms of Sun and Stars.) By Thomas E. Heath. (London: King, Sell and Olding, Ltd., n.d.) Price 3*s.* net.

In the first of these two volumes Mr. Heath has collected and amplified several articles which previously appeared in *Knowledge*, and in which he made a satisfactory attempt to bring home to the understanding of "the man in the street" the knowledge so far available as the result of the determinations of stellar parallaxes. It is, truly, as the subtitle indicates, a "road-book" in which the contours, or perhaps one should say the depths, as well as the directions, are plainly shown.

The text is really a simple, detailed description of the eight figures contained in the volume, all of which have been especially prepared by the author himself. Fig. 1 shows the sun and his attendant planets drawn to scale. In Fig. 2 the relative distances of all stars known to be within sixty light-years of our system are shown by placing the objects on a background formed by a map of the home counties, taking Greenwich as the point of departure,

the "sun-powers" of the various stars being represented by a system of symbols. Fig. 3 similarly treats all those stars within 480 light-years, a map of N.W. Europe constituting the background. The scale employed for the stellar distances is an interesting one, which takes as its unit the distance of a star situated at one light-year from the solar system. Mr. Heath fortuitously discovered that by calling this unit one mile the sun's distance is almost exactly represented by one inch.

Figs. 4 and 5, of which detachable duplicates are given in the book, present really beautiful pictures when used with a stereoscope, the star images standing out in numerous planes, some quite near to the eye, others apparently infinitely remote. The conception of the three-dimension character of space is most vividly impressed by these charts, the first of which represents the stars as viewed from a plane situated 500 light-years from the sun by eyes 107 light-years apart, the second a similar view at a distance of 100 light-years as seen by eyes 26 light-years apart.

The sun-powers of various stars are more especially dealt with in Figs. 6 and 7 and the accompanying text, whilst Fig. 8 represents a view of the known universe as it would appear to an external observer looking in the direction of R.A. 6h.

All the data (*e.g.* parallaxes, spectral types, sun-powers) used in constructing the various diagrams and discussed in the text, are given in tables which form an interesting and useful appendix to the volume. Avowedly written in a popular form, the book contains much that will not appeal to the astronomer, *e.g.* the reference to the Dogger Bank incident on p. 17, but should prove of interest and assistance to the amateur tourist in space by visualising the real interpretation of stellar parallaxes.

In the second of these two volumes Mr. Heath gives us a series of six stereoscopic charts of the sun and stars of which the parallax has been determined, similar to those mentioned above. The scale of the charts here given is one-fifth of that he employed for his large stereoscope, and in all of them the spectator's eyes are supposed to be 26 light-years apart, each drawing being made at any angular distance of 90 degrees from the four adjacent to it. Each view is accompanied by a table similar to those mentioned above.

The idea of representing stars in this stereographic manner is very ingenious, and this book, too, will certainly interest many astronomical readers.

PHYSICAL CHANGES IN IRON AND STEEL.

The Crystallisation of Iron and Steel. An Introduction to the Study of Metallography. By Dr. J. W. Mellor. Pp. x+144. (London: Longmans, Green and Co., 1905.) Price 5*s*. net.

THAT the students of the problems of metallography, particularly in the present unsettled state of affairs, should have for guides only those who have done some considerable amount of active work in the science will be readily acknowledged. A certain amount of familiarity with the metals themselves, their history and behaviour, is also necessary before the subject can be made to live. Reading through the present work convinces one that it is written by an onlooker, and the illustrations entirely support this view of the text. The presentation is without bias, and each theory and method is described and examined as clearly and fairly as the author's evident lack of practical acquaintance with the subject as a whole will permit. For anyone wishing to get an idea of what has been done and desiring a general survey of the scope of metallography, its theoretical aspect, and the problems it endeavours to solve, the book will serve fairly well. For the worker actually in the field, striving to progress in the science, to apply it to his own practical work with metals, and perhaps to endeavour by its aid to solve some of the difficulties that are ever confronting the metallurgist, it cannot honestly be recommended, as to such it will give but little light.

A few examples of the kind of thing encountered may be given. On p. 12, the recalescence curve of steel is shown as rising from 680° C. to about 810° C., whereas the real rise is only a few degrees; p. 14, "Ac2 is higher than Ar2"; p. 49, "excess of ferrite renders the steel ductile and tenacious," whereas pure iron has a tenacity of about 20 tons and pure pearlite of over 50 tons per square inch; p. 50, "2 per cent. carbon alloys are called cast iron" is quite wrong, for tons of steel are made with more than 2 per cent. carbon. Malleability is the essential point here. P. 52, discussing the influences which affect the physical properties, the author omits mechanical treatment—hot or cold work. "Heat white cast iron it forms grey cast iron" is quite misleading. P. 74, ii., is erroneous, and p. 76 is not in accord with the facts, as the writer has many times proved even in ordinary works practice, so there is only left the ingenuity of the explanation and the fact that it leads the reader astray. P. 81, "tenacity is lowered by silicon." Are the researches of Hadfield, Arnold, and Baker not sufficient to the contrary? Their results are not disputed. On p. 88, cleavage fragments are laboriously dealt with as crystallites. The reader is told they are perfect replicas of the larger crystal, and calcite is the example chosen! Sorby's samples are said to be 1 square cm. by 2 mm. thick. The originals are in front of the writer, and their surface area is more than 1 square inch. It may be of little importance, but the statement should either be near the truth or be omitted. P. 106, "the *cheapest* microscope, 16*l*. or upwards," and "it is necessary to have a brilliant light arc lamp, &c.," must discourage many isolated students, whereas much excellent work has been done and is being done with a batswing or a similar burner and a Beck's Star set at about 7*l*. P. 107, "microphotography."

A glossary gives the "nomenclature of metallography," and the present reviewer would like to study the faces of his colleagues of the Iron and Steel Institute's Committee on "The Nomenclature of Metallography" when they find that it is not based on the final report, but on the crude original put out expressly for discussion and amendment. The arduous session's work that followed was evidently

in vain so far as the author and his readers are concerned. The illustrations are taken from well-known workers, but at least the approximate magnifications should be given. Other points, owing to their importance, would require to be traversed in detail, but enough has been said to help those interested to judge whether the book would suit their purpose or not.

A. MCWILLIAM.

OUR BOOK SHELF.

Latins et Anglo-Saxons, Races supérieures et Races inférieures. By Prof. N. Colajanni. Translation by Julien Dubois. Pp. xx+432. (Paris: F. Alcan, 1905.) Price 9 francs.

SIGNOR COLAJANNI, a Socialist deputy and professor of statistics, is a convinced opponent of the doctrine of Anglo-Saxon superiority. The questions which he proposes to himself are, in brief:—(*a*) the meaning of the terms race and nation; (*b*) the existence of distinctive racial qualities; (*c*) the transmission of acquired qualities; (*d*) the equivalence of decadence in the nation and senescence in the individual. He concludes (*a*) that we have no data by which to determine the specific racial attributes of Sergi's European types; (*b*) that the terms superior and inferior, save as an expression of their relative positions at a given moment, have no meaning when applied to nations; (*c*) that acquired qualities are transmitted, especially when segregation favours fixation of the type; and (*d*) that decadence is relative, by comparison with the progress of other nations; nations may, phœnix-like, rise from their ashes and attain a second time to greatness.

Although Signor Colajanni's main arguments are derived from the English and Romance-speaking peoples of the present day, he does not hesitate to invoke the facts of ancient history and the non-European races, and his task is, in fact, one which demands the amplest equipment of historical, sociological, and economic knowledge, combined with an impeccable method and an unerring judgment. Let us illustrate his fitness for his task. A large part of the first half of this work is taken up with the proof of the first and second conclusions cited above; but his method consists largely in putting side by side two or more quotations, *primâ facie* contradictory, and drawing from them the conclusion that both or all are erroneous. He overlooks the fact that criteria are apt to differ; one author may assert the superiority of a race, another its inferiority; unless the standard is the same, the views are not even shown to be contradictory. Even were it otherwise, it is evident that of two contradictory assertions *both* are not necessarily wrong.

The statistical methods of the work are not above criticism; on p. 354 we have 110/3=22; on the following page there is a comparison of the material progress of France and England since 1840; for France the savings banks are included; the deposits show an increase of 2200 per cent. Signor Colajanni has no hesitation in taking this as an index number, but he does not add to the English table any corresponding figure for our savings banks; even, therefore, were it legitimate to take the mean of ten index numbers, regardless of their relative importance, as a fair statement of the changes. his method is ludicrously fallacious.

Signor Colajanni's knowledge of England is probably limited; we learn (p. 279) that our distinguishing traits are rudeness, lack of sociability, and pitilessness, and that these are due to fagging at school. Our lack of generosity and sweetness (*douceur*) are due (p. 124) to our games and violent exercise—football, of course, and perhaps lawn tennis, or, at an earlier age, battledore and shuttlecock. Of Signor Colajanni's logic we may judge when we read (p. 174 *et seq.*) of Anglo-Saxon decadence as visible in U.S.A., and later (p. 302) that only one-fourth of its citizens are Anglo-Saxons.

Signor Colajanni's book, though inaccurate, is not without its good points, but it leaves little permanent impression. The translator has little knowledge of English and German to judge by the strange words that often meet the eye.

N. W. T.

Machine Construction and Drawing. By Frank Castle, M.I.M.E. Pp. viii+275. (London: Macmillan and Co., Ltd.) Price 4*s.* 6*d.*

IN the study of machine construction and drawing the assistance to be derived from books can never be more than of secondary importance. The acquirement of a thorough knowledge of the subject depends principally upon the opportunities which a student may have of coming into daily contact in the workshop with varied examples of good engineering practice, and the use which he makes of these opportunities. Assuming that a youth is fortunately circumstanced, he will be busy at suitable moments compiling a book of miscellaneous notes, containing, amongst other things, many fully-dimensioned sketches taken from machine details lying around him. Along with this work, and very appropriately in the drawing class, he will make working drawings to scale of some of the things sketched in his notebook, and additional examples for sketching and drawing will be provided in the class.

The student will also consult text-books for further information, and the book under review will be found very suitable indeed for the purpose. The author first describes the necessary drawing instruments, and explains their use. He then sets out in detail, with proportional dimensions, various forms of common fastenings, such as rivets, bolts, keys, &c. Then come chapters containing examples of mill work, followed by others dealing with steam-engine details. The final chapter gives a short account of the physical properties of materials used in construction. Sets of useful exercises occur at intervals, and a few calculations of strengths are given; but the latter are wisely kept in strict subordination.

The drawings which abound throughout the work represent good practice, are fully dimensioned, very clearly printed, and will be appreciated by teachers and students alike.

While not free from minor defects, the book can be cordially recommended for use in drawing classes, and to young engineers who are seeking after knowledge on which to base subsequent work in machine design.

Graphs for Beginners. By W. Jamieson, A.M.I.E.E. Pp. 64. (London: Blackie and Son, 1905.) Price 1*s.* 6*d.*

IN order to teach and illustrate the subject, the author in this small volume makes use of a number of interesting graphs relating mainly to technical and commercial subjects, many of them discontinuous, algebraical curves being given only a secondary place, though the logarithmic or compound interest law is dealt with. The significance of the slope at any point of a graph is enforced by simple and effective examples. The treatment is suggestive and interesting, and the author is justified in hoping that the book will tend to cultivate the observation and stimulate the reasoning powers of the young readers.

The Preservation of Native Plants and Animals.

FROM London papers recently to hand, I see that at the ornithological congress, on the motion of the Hon. W. Rothschild, a resolution was forwarded to the Premier of New Zealand in regard to the importance of taking steps to preserve and protect the birds on the Auckland and Campbell Islands.

It may be of interest to ornithologists in Great Britain to hear that our local scientific societies had already, in May, memorialised the Government to the same effect; indeed, we asked that protection should be afforded, not only to the birds, but also to the flora.

We have likewise forwarded a similar resolution to the State Government of Tasmania in respect of the penguins on the Macquarie Islands.

The resolution, therefore, of the ornithological congress should strengthen the hands of our local institutes, which bodies are keenly alive to the importance of preserving, as far as possible, the fauna and flora of New Zealand.

The Government, too, has hitherto met our requests in a prompt and generous manner. A couple of years ago, for example, the Otago Institute pointed out to the Minister for Lands that sheep were destroying the alpine flora of the Southern Alps, especially in the region around Mount Cook; the Government at once proclaimed the area as a "reserve," and the sheep were banished.

In fact, the Government is remarkably ready to afford any protection that is possible; and the recent proclamation of the whole of the S.W. portion of the South Island—including the Great Lakes, a vast mountainous, forest-clad area, and the famous fjords—as a "national park," and the prohibition of the use of guns and dogs herein, has already had its effect in the increase in number of some of our rare birds.

You will see, therefore, that we out here, equally with naturalists at home, have at heart the interests of our native plants and animals. W. B. BENHAM.

Otago University Museum, Dunedin, N.Z., August 21.

The Omission of Titles of Addresses on Scientific Subjects.

I VENTURE to ask the attention of "whom it may concern" to the practice in vogue in Great Britain of publishing presidential addresses of scientific societies and of sections of the British Association without any mention of the titles of those addresses. Take, for example, a case quite at random, but just at hand. NATURE of August 17, beginning on p. 368, contains the inaugural address of the president of the British Association with the heading "Part I." On p. 372 of the same number is another presidential address without a title. On p. 378 a third address has no general head, but it has the distinct advantage of four subheads that enable the reader to select at a glance what he wants, and to pass over other matters if he so chooses.

Unfortunately these are not exceptional cases. I have in my library scores of these addresses in the form of separates without a word on the title-page to indicate how they are to be classified in a library. The presidential addresses published in the reports of the British Association are conspicuous examples of this kind of publication. I have taken the trouble to look through these reports from the beginning of the association in 1831 down to 1892, and out of all the addresses of the presidents of the association published in these sixty-one years there are only five that have titles or subtitles. These are the addresses given in 1831, 1839, 1854, 1880, and 1885.

It is easy to see how this absence of title came about originally, but, as seen from this respectful distance, the history of it is nothing to the point. What this busy world wants is help to get at what we are interested in with the least possible waste of time.

This hot haste may seem unbecoming to men of science, or perhaps it may appear that we Americans are in too big a hurry—that we are too much impressed with the motto "time is dollars." But we are not spending all our time chasing the dollar; there are many other nimble things that we are trying to keep up with, and one of them is the progress of science in Europe, along the lines in which we are especially interested.

If a member of so young and giddy a nation might venture to make a suggestion to older and wiser people, it would be in favour of requesting or requiring the presidents of the various scientific organisations and sections of the British Association to provide headings for their addresses so that those of us who have not the time to read all these good things may be able at a glance to pick out what we want especially to see. As matters now stand we are compelled, as a rule, to do one of two things—either to let them all go unread—to our great regret and loss—or to wade through pages upon pages of matter which, however valuable it may be, is out of our line and of no especial interest to us. Such titles, headings or subheads as are here suggested would avoid these difficulties. It would not cost much; it would not take much time, and it would save much of ours and some of your own. We appeal to you for sympathy and help.

JOHN C. BRANNER.

Stanford University, California, September 7.

Protective Coloration of the Inside of the Mouth in Nestling Birds.

THE habit shown by many helpless nestlings, of gaping widely when the nest is approached, is usually explained by supposing that the birds are appealing for food. This explanation has always seemed to me inadequate, for nestlings that gape usually have the inside of the mouth brightly coloured, and in some cases marked with conspicuous spots. Moreover, newly hatched nestlings among the Passeres gape if the fingers are snapped just above them, or if the branch bearing the nest is shaken. It seems a fair inference, therefore, that the act of gaping is often, if not usually, an expression of alarm.

In order to test the effect of the widely opened and brightly coloured mouth, I have several times asked young children to touch the edge of the nest or place a finger in the mouth of one of the birds, and from their hesitation or even refusal to obey I am convinced that the conspicuous coloration, by centering attention upon the gaping mouth, tends to protect the nestling from molestation. Mr. W. P. Pycraft thinks that the bright colours and spots are "guide-marks" to facilitate the proper placing of the food in the mouth by the parents. But persons who rear nestlings find no difficulty in feeding them so long as they gape freely, without troubling themselves about placing the food in any particular region of the mouth. W. RUSKIN BUTTERFIELD.

4 Stanhope Place, St. Leonard's-on-Sea.

Helmert's Formula for Gravity.

ON p. 79 of Everett's valuable "Illustrations of the C.G.S. System of Units with Tables of Physical Constants" (London: Macmillan and Co., Ltd., 1902) the following lines occur:—

"In a Report now printing, which will contain a very full list of results, Helmert adopts, as the most accurate general formula for g reduced to sea level,

$$g = 980.617\,(1 - 0.002644 \cos 2\phi + 0.000007 \cos^2 2\phi).$$

. . . . This may be accepted as the best general formula yet put forward."

The formula alluded to was given first by Helmert in his paper "Der normale Theil der Schwerkraft in Meeresniveau" (*Sitzungsberichte der k. Preussischen Akademie der Wissenschaften zu Berlin,* 1901, xiv., pp. 332–336), but with a different coefficient, namely,

$$g = 980.632\,(1 - 0.002644 \cos 2\phi + 0.000007 \cos^2 2\phi),$$

and it is not reproduced in the report mentioned in the above quotation from Everett, but in a subsequent one (*Comptes rendus des Séances de l'Association Géodésique Internationale,* Copenhagen, 1903, ii., p. 42, Berlin, 1905).

THE FAYUM.[1]

THE palæontological treasures yielded by the Fayum have made that Egyptian province no less famous among geologists and zoologists than are the "bad lands" of the United States territories, the Sevalik Hills, or Pikermi. The discoveries by Messrs. Beadnell and Andrews of extinct mammals, the study of which serves to clear up the whole question of the ancestry of that strangely specialised group the Proboscidea, are not of less significance than those which enabled Marsh and Huxley to demonstrate how the equally aberrant type of Equidæ originated.

We are glad to learn from the introduction to the present volume that the whole mass of palæontological material which has been obtained by the Egyptian Government has now been handed over to the authorities of the British Museum for the purposes of study and description. While the type-specimens will, we understand, be eventually deposited in the museum at Cairo, a good representative series of duplicates will be retained in this country.

Preliminary notices by Dr. Andrews and Mr. Beadnell himself concerning the osteology of some of these curious extinct forms of mammalian life have already appeared, but for the full details we must await the promised publications to be issued by the trustees of the British Museum. In the meanwhile, we welcome the volume before us, which gives a very clear and suggestive account of the general features of the district in which these splendid discoveries have been made.

The Fayum is a circular depression in the Libyan Desert, having an area of more than 3000 square miles, and is situated to the west of the Nile, some distance south of the latitude of Cairo. The lowest part of the district is occupied by the lake known as the Birket el Qurun, which has an area of between 80 and 90 square miles; but this area appears to be continually diminishing owing to evaporation. On the south-east side of the lake lies a tract of cultivated land, covered with alluvium similar to that of the Nile Valley, and having an area of about 700 square miles. The cultivated area is directly connected with the Nile Valley by a depression through which runs a natural canal—the Bahr Yusef—which conveys water to the Fayum and irrigates the whole of the district.

The remaining area of the Fayum is practically desert, the most interesting part of this desert area being two deep dry depressions in the south-west known as the Wadi Rayan and the Wadi Muêla. These depressions have attracted a considerable amount of attention from engineers in recent years, as being possibly capable of conversion into reservoirs for the purposes of irrigation.

Until the year 1898, when the examination was commenced by the Geological Survey of Egypt, little was known concerning the geology of this district. It was crossed in 1879 by Dr. Schweinfurth, who discovered bones of the extinct cetacean Zeuglodon, and this seems to have been the first indication of the existence of vertebrate fossils in the district. Soon after the commencement of the survey by Mr. Beadnell, under the direction of Captain Lyons, the remains of fish and crocodiles were found to occur in the beds of the Middle Eocene, which had yielded the fossils found by Schweinfurth. A few fragments of bone were also found in the Upper Eocene strata, but it was not until 1901, when Dr. Andrews, of the British Museum, had joined Mr. Beadnell for the purpose of collecting recent North African mammals, that the outcrop of strata was crossed upon which a considerable number of mammalian and reptilian remains lay exposed, many in an excellent state of preservation. Energetic efforts on the part of the authorities of the British Museum and the Egyptian Government have resulted in the rich harvest of palæontological treasures now awaiting description, some of which are familiar to all visitors of the Natural History Museum at South Kensington. The study of these extinct types of mammals and reptiles, in addition to affording much new light on the evolution of living forms, cannot fail to increase greatly our knowledge of the successive stages by which the present distribution of these forms of life has been reached.

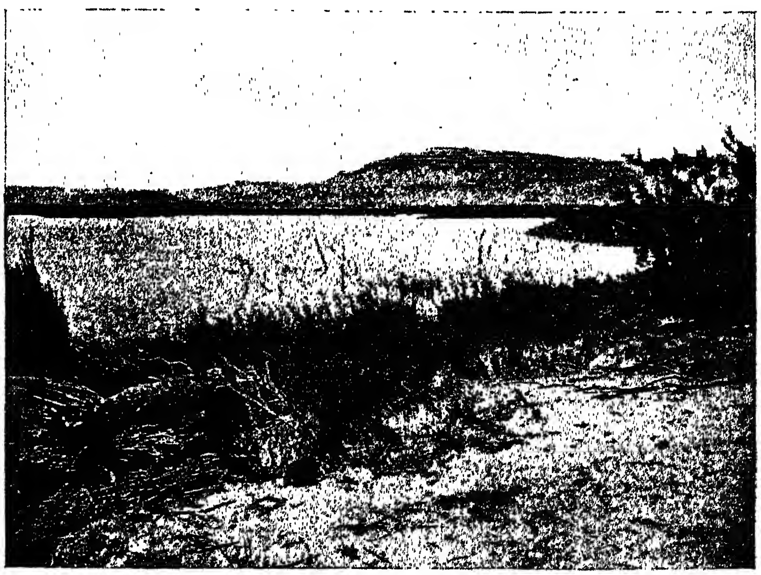

FIG. 1.—North side of the Birket el Qurun, looking West. From "The Topography and Geology of the Fayum Province of Egypt," by H. J. L. Beadnell.

The series of strata which have yielded the interesting vertebrate faunas is clearly described by Mr. Beadnell in the work before us. The beds are admirably exhibited in a number of fine escarpments. At the base are found Middle Eocene (Parisian) strata with an aggregate thickness of about 1300 feet. Nummulites and mollusca abound in these beds, which in their lower part contain Zeuglodon and fish remains, and in their higher portion the older of the two vertebrate faunas. The Upper Eocene (Bartonian) which overlie these have a thickness of 830 feet, and, with some remains of mollusca, yield the abundant remains of the second vertebrate fauna. No Miocene strata have been found in the Fayum, but about 100 feet of fluvio-marine beds, intercalated with contemporaneous (interbedded) sheets of basalt, and containing silicified trees, are referred to the

[1] "The Topography and Geology of the Fayum Province of Egypt." By H. J. L. Beadnell, F.G.S., F.R.G.S. Quarto. Pp. 101. Plates 24. (Cairo: National Printing Department, 1905.)

Oligocene (Tongrian). The youngest beds in the area are gravel terraces, lacustrine clays, deposited on the bed of the ever-diminishing lake, sands blown from the desert, and alluvial deposits.

Mr. Beadnell adduces evidence in favour of the view that the bodies of the animals the skeletons of which are found entombed in the strata of the Fayum were brought down from the African interior by a great stream which flowed in a north-westerly direction, passing through the ancient lake occupying the site of the Baharia Oasis. At that period the shore-line would be near the Fayum, and the Nile would flow into the sea near the same point.

In historical times, as is well known, a large part of the Fayum was occupied by the ancient Lake Moeris. By successive reclamations of the alluvial lands, this lake has probably been reduced to less than one-eighth of its original area, and now constitutes the comparatively insignificant Birket el Qurun.

The work before us appears in the same excellent form as the other memoirs of the Geological Survey of Egypt, issued under the direction of Captain Lyons. There are sixteen plates reproduced from photographs, which give a good idea of the scenery of this wonderful district. We give reductions of two of the plates. In addition to these, there are two geological maps and six sheets of longitudinal sections. There are also woodcuts in the letterpress. The printing of the text of the work and the execution of the illustrations are highly creditable to the Survey Department at Cairo.

THE ROYAL PHOTOGRAPHIC SOCIETY'S EXHIBITION.

THE fiftieth annual exhibition of the Royal Photographic Society is now open. There is a distinct and regrettable falling off in the number of exhibits in the section devoted to scientific and technical photography, but this is in a measure compensated for by the presence of the loan collection of British photographs of a similar kind that was sent to the St. Louis Exhibition last year, though among the latter there are many examples that have been shown in the society's previous exhibitions.

Of the new work, the natural history section is by far the best represented. Miss Turner's set of photographs of the "great crested grebe," and a series of twenty-two lantern slides of butterflies by Dr. D. H. Hutchinson, have been awarded medals. The lantern slides are by the Sanger-Shepherd three-colour process, and illustrate the usefulness of this method for recording rare varieties. In some of the slides the colours are notably excellent, perhaps as perfect as any mechanical colour process will ever produce. Some of the photographs of "nesting swans" by Mr. Douglas English must have been taken at considerable risk, for in two or three of them the bird is shown flying at the photographer in anger. Another example (No. 237) will be found in the west room among the pictorial photographs, and close by (No. 216) is a very fine photograph of sea-gulls, the foremost of which are in the act of alighting on the water. Of other photographs that record slower movements, the chief are a series of seven by Mr. W. Farren of the "skin moult of the caterpillar of the privet hawk-moth," a series of eight photomicrographs (×30) by Mrs. Kate J. Pigg showing the germination of a grass seed, and two photographs of the same oak, the one taken more than fifty years before the other, by Mr. J. B. Hilditch. The earlier photograph of the oak was exhibited at the first exhibition of the Royal Photographic Society (then the Photographic Society of London), and is at least as good a piece of work as the later, the main difference from a technical point of view being that the exposure necessary for the first was three thousand times as long as that given for the second. There are many other photographs of living things, but the bee photographs of Mr. Oliver G. Pike deserve special notice. The difficulty was to get light enough without causing the bees to stop their work, and Mr. Pike has succeeded.

Of other work in the technical section there are photomicrographs showing the structure of various metals and alloys by Mr. E. F. Law, some interesting wave photographs by Dr. Vaughan Cornish, and a number of radiographs by Dr. Thurstan Holland which well illustrate the possibilities of modern methods. The only "natural colour" photograph that we discovered, other than the transparencies by the Sanger-Shepherd method, is a three-carbon print by Mr. Brewerton. We think he has sent as good examples in previous years, but whether or not, what we want to show the capabilities of three-colour work are the finished print, produced without handwork, by the side of the object or painting that it represents. Some commercial work is excellent, but its measure of perfection is due to retouching.

The loan collection from the St. Louis Exhibition will doubtless prove more interesting to many than the new work, because of its greater variety. Some of these exhibits are of historic interest, such as Sir William Abney's photograph of the spectrum in the infra-red, and General Waterhouse's examples of photomechanical work. There are a very great many

photomicrographs of etched metals and alloys, some astronomical and spectrum photographs, and Mr. Edgar Senior's photomicrographs of sections of photographic films, including those of colour photographs by Lippmann's process which demonstrate that the silver deposit is in layers.

In the trade section there are many interesting exhibits. Doubtless the greatest novelty is the demonstration of the three-colour process called "pinatype," which is claimed to be the amateur's method of colour printing on paper. Three prints in chromated gelatin are made from the ordinary three transparencies, and these are each caused to absorb its proper colour by soaking it in the proper dye solution. The prepared paper that is to bear the print is squeegeed on to each of these coloured "print plates" in turn, and duly absorbs the colour. Thus the three colours are absorbed into a single film. The examples we saw were of various degrees of merit.

PROF. LEO ERRERA.

LEO ERRERA, professor of botany in the University of Brussels and member of the Royal Academy of Belgium, whose death on August 1 has already been announced, was born in 1858. He merited preeminently the title of professor, for not only was he gifted as few men are gifted with the faculty of giving a clear and precise explanation of complicated problems, and of impressing upon the minds of his hearers his conclusions, which were well reasoned and supported by facts and conceptions, but he was also one of those teachers who recognised that it is not possible to improvise a lecture, however simple or commonplace, without bestowing upon it lengthy and conscientious preparation. In addition to the critical judgment which characterised his teaching, he always kept it abreast of scientific knowledge; each year, even in the case of his elementary courses, his lectures were looked through, revised, and brought up to date so as to include the latest results in the subject.

Prof. Errera was one of the first teachers in Belgium who had the courage to declare that practical work should take precedence of theoretical studies, which alone had formed the ordinary courses up to that time. He was convinced that a student should only accept as true what he had verified for himself, and that it is not sufficient to know scientific results without becoming acquainted with the methods employed. With this object he established in 1884, when he was appointed professor in the university, the laboratory for vegetable anatomy and physiology which became later the Botanical Institute.

He was wonderfully assisted by the remarkable facility with which he assimilated all current literature. He read Danish and Swedish without any difficulty, and at the congresses in which he took part, whether English, German or Dutch, he invariably excited admiration by his correct and expressive rendering of foreign languages. It was not surprising that at the International Botanical Congress held at Vienna last June he was nominated president for the next congress, to be held at Brussels in 1910.

The worries of teaching did not cause Errera to forget that it is the duty of every scientific man to contribute to the increase of that knowledge which has been handed down to him. His energy was especially productive along four lines of research.

When Darwin had attracted attention to the importance of cross-fertilisation among plants and to the part played by insects in the transfer of pollen, Errera as early as 1878, recognising the full import of this discovery immediately set to work to study with his keen experimental insight the genera Penstemon and Primula, and *Geranium phaeum*.

Later, while he was working in De Bary's laboratory at Strasbourg, he discovered in certain fungal cells a substance then unknown which gave all the reactions of glycogen. This is a body allied to starch that was conclusively shown by the great Claude Bernard to be of great importance in animal physiology. By degrees Errera recognised glycogen in all the groups of fungi, and was able to assign to it the same function, *i.e.* that of reserve carbohydrate, as it has in animals. His first researches on this subject were published in 1884, and constituted his thesis for admission into the University of Brussels.

Prof. Errera initiated a series of papers on the *rôle* of alkaloids in plants. The origin and *rôle* of these poisons in plant economy formed, and still forms, the subject of discussion. The papers of Errera and his pupils tend to prove that alkaloids are decomposition products of nutrition, but that they may be utilised by plants as a defence against herbivorous animals.

He was one of those who realised the importance which attaches to molecular forces in the structure of living beings and in all the obscure phenomena of nutrition. Basing his investigations primarily on the important works of the physician Joseph Plateau, the illustrious professor of the University of Ghent, Errera showed that cellular membranes behave in the same way as if they obeyed the laws which regulate the reaction of liquid films such as are produced in blowing soap-bubbles. His first communication on this subject dates from 1886.

But not content to lead the way in the domains of science which we have outlined and to direct the work of his students therein, he also pursued many investigations in very diverse subjects. He did much to improve the methods of microscopical technique; he simplified greatly the microchemical examination of certain substances; he published ingenious theories on the mechanism of sleep, and contributed lectures on widely different subjects varying from pedagogy to natural philosophy; and all his publications were marked by a clearness and purity of style that are not surpassed in the writings of any other man of science.

JEAN MASSART.

NOTES.

MR. G. B. BUCKTON, F.R.S., author of several monographs on entomological and other subjects, died on September 26, at eighty-eight years of age.

WE regret to see the report that Sir William Wharton, who was prevented by illness from leaving Cape Town with other members of the British Association last week, is suffering from enteric fever complicated by pneumonia. His condition on Monday showed a slight improvement.

AN earthquake shock was felt in Stirling, Dollar, and Alloa shortly before midnight on Thursday, September 21. The shock travelled in a similar direction to that of July 23, namely, to the south-east, but it was of slightly longer duration and more violent in character. In Stirling pictures and crockery were shaken and articles of furniture moved, and a sound like thunder was heard. At Corton railway signal-cabin all the bells were set ringing. At Bridge of Allan the shock was felt very decidedly. In Bannockburn and in the neighbouring villages the impression was of a serious explosion. Comrie was only slightly affected: a low rumbling sound was heard, but no damage was done.

AN electrical exhibition on a large scale was opened at Olympia, Kensington, on September 25 by the Lord Mayor of London. The exhibition is under the auspices of the National Electrical Manufacturers' Association (Incorporated), and is intended to demonstrate the powers and uses of electricity in domestic, manufacturing, and commercial directions. Among the special exhibitors are the General Post Office and the Marconi Company. The Institution of Electrical Engineers is taking an interest in the exhibition on the educational side; and a series of popular scientific lectures and demonstrations has been arranged upon wireless telegraphy, electric motor developments, domestic lighting, telegraphy, telephones, and other subjects.

IN NATURE of July 13 (p. 244) there appeared a letter by Mr. Rotch, director of the Blue Hill Meteorological Observatory, U.S.A., describing the Franco-American expedition for the exploration of the atmosphere in the tropics which was sailing on M. Teisserenc de Bort's steam yacht *Otaria*. During a two months' cruise, the scientific members of the expedition, Messrs. Maurice, of Trappes Observatory, and Clayton, of Blue Hill, executed thirty-two soundings with balloons and kites, and made observations on two tropical peaks, all between latitudes 9° and 37° N. and longitudes 16° and 31° W. A southerly or south-westerly return trade was found at a height of about two miles in the tropics and an easterly wind in the equatorial regions, confirming the generally accepted theory of atmospheric circulation. While the detailed observations are to be published in a special volume by Messrs. Teisserenc de Bort and Rotch, the general results of the investigation will, it is hoped, be embodied in an article which will appear in the columns of NATURE.

THE first congress of the International Surgical Society was held from September 18–22 at the Palais des Académies in Brussels under the patronage of King Leopold. A correspondent of the *Times* says that more than two hundred delegates attended, representing the following countries:—Great Britain, France, Germany, Austria-Hungary, the United States, Belgium, Holland, Switzerland, Japan, Russia, Spain, Portugal, Sweden, Norway, Italy, Denmark, Greece, Finland, Rumania, Servia, and Egypt. The subjects discussed were of a purely technical order, and papers were read on the latest development of surgical science. An interesting feature of the congress was an exhibition of the latest surgical appliances. The delegates received a cordial welcome from the Government and municipal authorities and from their local colleagues. The last meeting of the congress was held on Saturday, September 23. During the session a congratulatory telegram was sent in the name of the society to Lord Lister on the great progress of surgery directly resulting from his antiseptic discoveries. It was resolved that the second congress should also be held in Brussels in 1908. Prof. V. Czerny, professor of surgery in the University of Heidelberg, was appointed president, and the various national committees were also nominated.

THE *Victorian Naturalist* announces the death of Mr. H. T. Tisdall, formerly president of the Field Naturalists' Club of Victoria, and an active botanical teacher and investigator. In September, 1883, he contributed his first paper to the club, the title being "A Botanical Excursion in North Gippsland." Having to a great extent exhausted the phanerogams of the district, he was induced by Baron von Mueller to turn his attention to the cryptogams, with the result that he became an authority on fungi, and at the meeting of the club in February, 1885, contributed a paper entitled "The Fungi of Mt. Baw Baw," in which he described some twelve species of the genus Agaricus. In November of the same year he contributed a further paper on the fungi of North Gippsland, in which he made some important remarks regarding the fungus then known as *Mylitta australis*, "Native Bread." During the interval of nearly twenty-one years between his first and last papers, he contributed numerous papers to the meetings of the club, all relating more or less to botany, either as bearing on a particular branch or descriptive of trips or excursions in search of specimens. In addition to his knowledge of Victorian phanerogamic and cryptogamic plants, Mr. Tisdall was, at the time of his death, an authority on marine algæ. He contributed an article on the flora of Walhalla to the mining department's report on that goldfield (1902), as also some useful papers to the meetings of the Australasian Association for the Advancement of Science, which included a list of the marine algæ of Victoria.

IN *l'Anthropologie* (xvi., No. 3) M. Boule gives a more detailed account of the machine-made eoliths referred to in his paper in the *Comptes rendus*, translated in NATURE of August 31 (p. 438). From the descriptions and illustrations, it appears that among the specimens collected

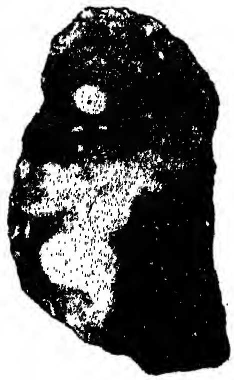

FIG. 1.

FIG. 2.

by M. Boule in a few minutes from the great pile of refuse flints are all the forms regarded as characteristic of eoliths. In particular, we find the bulb of percussion present in more than one example; one of these, shown in Fig. 1, is remarkable for what would, in an artificial

FIG. 3.

flint, be called "beauty of work" on one of the edges (Fig. 2); others, of which Fig. 3 is a good example, show the notch, which, like the bulb of percussion, is commonly regarded as a criterion of human workmanship. From the researches of M. Boule, it seems that the eolith should

no longer be cited in proof of human antiquity greater than can be assumed on other grounds. Eolithic forms may be due to human agency, but independent proof of the contemporary existence of man in the area in question is henceforth indispensable.

THE latest issue (vol. viii., part i.) of the *Transactions of the Norfolk and Norwich Naturalists' Society* contains a number of interesting papers, mostly dealing with the natural history and antiquities of the county. The papers on local biology include one on the water-beetles of the "Broads" by Mr. F. B. Browne, another on the hydrachnids of the same district by Mr. C. D. Soar, notes on the Yarmouth herring-fishery of last year by Mr. T. J. Wigg, lists of Norfolk lichens and liverworts by the Rev. E. N. Bloomfield, and an account of the rotifers of the county by the Rev. R. Freeman.

WE have received from Dr. E. M. Goeldi, director of the museum at Parà, a budget of separate copies of papers by himself, published, with the exception of one, in the *Comptes rendus* of the sixth zoological congress held at Berne last summer. The one exception is from the *Ibis* for April, and deals with the habits of a Brazilian tyrant-bird (*Myiopatis semifusca*); this species, in place of being insectivorous, feeding on the fruits of a parasitic plant and disseminating the seeds, thus causing harm to arboriculture. The other papers relate to rare animals from Amazonia, the yellow-fever mosquito (*Stegomyia fasciata*), and the habits of ants of the genus Atta.

WE have received two new parts of the reports of the scientific results of the voyage of the *Belgica*, 1897–9, issued at Antwerp, in one of which Prof. H. Leboucq discusses the development of the flippers of Antarctic seals from the point of view of the evolution of the pinnipeds in general, while in the second Mesdames Bommer and Rousseau describe the funguses collected during the cruise, all of which, with the exception of a single Antarctic specimen, were obtained from Tierra del Fuego. Judging from the collection, the fungus-fauna of the latter area appears to be a rich one of which but little is at present known. Prof. Leboucq's article is the first of a series on the "organogenie" of the seals. In the case of both memoirs we may direct attention to the difficulty they present to recorders of biological literature, or, for that matter, to anyone who desires to quote from them. They are respectively headed "Zoologie" and "Botanique," but, despite the fact that they are not the first issues of those two series, each is separately paged, and neither bears any volume number. Consequently the whole title has to be quoted for reference purposes.

ACCORDING to the report for the year ending in May last, the Rhodesia Scientific Association, now in the seventh year of its existence, continues to make satisfactory progress, both as regards the length of its roll of members and in the work accomplished. With the report we have received a copy of the fourth volume (1903–4) of the association's Proceedings, which contains a number of papers dealing with the biology and antiquities of the country, together with one on its soils. The latter do not appear to be so promising as might have been hoped, most of them possessing only a moderate degree of fertility, and none exhibiting that redundant growing capacity we are accustomed to associate with virgin lands. Perhaps the most generally interesting paper is one on a new gladiolus which grows in the spray of the Victoria Falls, and has therefore been called the "Maid of the Mist." Four bulbs were sent to England, where by aid of constant syringing they were induced to bloom in a hothouse, when it was found that the petals are so arranged as to form a kind of penthouse for the protection of the central organs from the constant shower-bath existing in the "rain-forest."

AN important issue of the *Palaeontologia Indica* (*Mem. Geol. Survey of India*) is devoted to the description of some recently discovered vegetable and vertebrate remains from the permo-Carboniferous strata of the Vihi Valley, fifteen miles to the south-east of the city of Srinagar, Kashmir. The remains in question were discovered by Noetling in beds apparently underlying the marine Kuling series (Permian) of the Kashmir Valley; and as they include a member of the "glossopteris flora" of the Lower Gondwana system of peninsular India, their discovery serves to confirm the reference of these deposits to the Upper Palæozoic. The plant remains, which are described by Mr. A. C. Seward, include only one generically determinable type, namely, Gangamopteris, from the base of the lower Gondwanas of the peninsula. The vertebrates, for the identification of which Dr. A. S. Woodward is responsible, include a couple of species of the palæoniscid ganoid genus Amblypterus, nearly allied to Lower Permian from Rhenish Prussia, and fragments of a labyrinthodont amphibian apparently referable to Archegosaurus, a genus known elsewhere only from the last mentioned and equivalent formations. No reference is made to the labyrinthodont from the Lower Gondwanas of the peninsula described as Gondwanosaurus, but originally referred to Archegosaurus.

IN the third part of his contribution to the study of the mischievous insects commonly known as leaf-hoppers and their enemies, published at Honolulu as part iii. of the first Bulletin of the Experiment Station of the Hawaiian Sugar-Planters' Association, Mr. R. C. L. Perkins furnishes some very interesting information with regard to the life-history of the parasitic Stylopidæ (Strepsiptera). It appears that although the majority of those degraded beetles infest bees and wasps, a certain number of species are parasitic on leaf-hoppers and other Homoptera, and it is the latter that form the subject of the communication before us. Although death usually follows some time after being "stylopised," many leaf-hoppers are able to procreate their kind after being badly affected by the parasites, especially if by females. The male stylopids, on account of the larger size of the puparia, are, however, much more speedily fatal to the leaf-hoppers, the hole left in the bodies of the latter by the escaping insect being relatively large. Moreover, a fungus immediately makes its appearance, with fatal effect, in the tube; and in artificially infecting leaf-hoppers with stylopids it is considered of the highest importance that the fungus should also be introduced.

THE report on economic zoology contributed by Prof. Theobald, of Wye Agricultural College, to the college journal for the year 1904–5 deals chiefly with the insect pests of field and garden crops, and on this important subject gives a great deal of useful information. During the year Prof. Theobald dealt with about 1200 communications, and his report contains descriptions of the most troublesome pests brought to his notice. Among the pests of fruit trees, the apple aphides *Aphis pomi, A. sorbi,* and *A. fitchii* were much the most destructive. Prof. Theobald points out that these forms have been wrongly described as a single species, *A. mali,* by previous English writers. The aphides do great damage to young shoots, leaves, and blossoms, but it is apparently hopeless to attempt to get rid of them by spraying in the usual

way in spring. The only practical remedy, especially where the first two species are concerned, is to spray in autumn, and a heavy paraffin emulsion is recommended, as injury to the leaves is not a serious matter at this season. The work is troublesome but effectual. In many cases it may be possible to collect and burn affected leaves in autumn, and this is recommended. Prunings should also be burnt before March. In the same report Prof. Theobald mentions a case in which honey-comb was destroyed by the maggots of the window fly (*Rhyphus fenestralis*). The window fly is a very common insect, but has never before been reported as an enemy of the bee, and the case is mentioned as showing how a harmless insect may suddenly change its habits and become a pest.

Two recent botanical parts, Nos. 9 and 11, of vol. xii. of the *Proceedings of the American Academy of Arts and Sciences* deal with systematic work. In the one number Mr. B. L. Robertson collates some American Eupatorieæ, and Mr. J. M. Greenman presents a list of new flowering plants from Mexico and the south-western United States. In addition to the new species, Mr. Greenman proposes two new genera, Lozanella, near to Trema, of the order Ulmaceæ, and Mimophytum, a borraginaceous genus allied to Omphalodes and Cynoglossum. The other part contains the sixth and last of the preliminary diagnoses by Prof. R. Thaxter on new species of Laboulbeniaceæ, a specialised group of minute ascomycetous fungi which live parasitically on insects.

SEVERAL points of interest are noted in a phyto-geographical sketch by Dr. L. Cockayne of the vegetation of the two Open Bay islands, which lie close to the shore of South Westland, a county in the southern island of New Zealand. Characteristic liane formations occur on both islands; on the larger northerly island the dominant liane is a screw-pine, *Freycinetia Banksii*, and in some parts, *Muehlenbeckia adpressa*, of the order Polyonaceæ, is associated with it or takes its place; on the smaller island the Freycinetia is absent, and the Muehlenbeckia forms pure scrub or grows with a large-leaved variety of *Veronica elliptica*. The account appears in the *Transactions of the New Zealand Institute* (vol. xxxvii.), as also a list of newly-recorded habitats for New Zealand plants by the same writer. The identification of a Carex from Chatham Island, as a variety otherwise only recorded from Patagonia, adds another to the list of plants which connects the floras of New Zealand and South America.

AT the age of four score years, Dr. v. Neumayer has the satisfaction of issuing the third edition of his "Anleitung zu wissenschaftlichen Beobachtungen auf Reisen." It is appearing in parts (Jaennecke, Hanover) at a price of 36 marks, and will comprise two volumes, the first dealing with geography and inanimate nature, the second with plants, animals, and man. More than thirty experts are collaborating under Dr. v. Neumayer's editorship, so that each subject will be treated by an expert. The first two parts have already appeared, and contain articles on geographical observations, directions for somatological observations, an anthropological questionnaire, which seems to be identical with that issued by the Berlin Museum for Africa, and, finally, the commencement of an excellent article by Dr. v. Luschan on field work in archæology. No provision seems to be made for an article on a traveller's outfit or general hints; but it would not materially increase the size of the book to do so, and probably its general usefulness would be much increased by the addition. The last edition appeared in 1888, and in many branches of knowledge the advance since that date has been immense. It is therefore a matter for congratulation that Dr. v. Neumayer has been able to supervise the re-issue and gather around him so many able coadjutors.

A COMMISSION has been appointed by the Lieutenant-Governor of the Transvaal to consider the question of the safety of persons travelling in shafts. It will inquire into the structure, material, preservation, and examination of winding ropes and the adaptability of safety catches.

MESSRS. PERCIVAL, MARSHALL AND CO. have published a useful little guide to standard screw threads and twist drills by Mr. George Gentry. Tables are given of the Whitworth standard thread, the British Association standard, bicycle screw threads, the V standard thread, the United States standard thread, the international metric standard thread, watch and clock screws, and twist drills. The guide, which is published at 6*d*. net, is specially designed to meet the needs of the model engineer, and shows in a striking manner the necessity for the general adoption of standard threads as advocated in an article recently published in NATURE (August 31).

THE current issue of the *Bulletin de la Société d'Encouragement* contains an important memoir by a Swedish engineer, Mr. Hjalmar Braune, on the influence of nitrogen on iron and steel. That metalloid exerts an influence more harmful even than that of phosphorus, and appears to be the chief cause of the fragility of mild steel. Its presence in iron is not due to the direct combination of the metal with the nitrogen of the air; the intervention of basic slag is necessary. Metal made by the Thomas and Gilchrist process contains more nitrogen than steel made by the acid process, and this explains the inferiority generally ascribed to the former material.

THE annual report on the mineral resources of the United States for 1903 has been issued under the able editorship of Dr. David T. Day. It forms a bulky volume of 1204 pages, and contains, in addition to statistics of production, a large amount of descriptive and technical matter. In 1903, for the fourth time, the total value of the United States mineral production exceeded 200,000,000*l*., iron and coal being the most important of the mineral products. The United States in 1903 were the greatest producers of iron, coal, copper, lead, petroleum, and salt in the world. Tin, it is interesting to note, has been found in commercial quantities in South Carolina, and the mines were actively worked in 1903. The manufacture of arsenious acid, a new industry in the United States, is carried on at Everett, Washington. The production of gypsum continues to show a remarkable increase, owing, doubtless, to the use of plaster of Paris in large modern buildings. There was, too, a notable increase in the production of the ores of nickel, cobalt, chromium, tungsten, molybdenum, vanadium, titanium, and uranium owing to their use for steel-hardening purposes. A great advance in the lapidary industry is also reported. The fact that larger establishments have been formed, which are able to purchase the rough diamonds in greater quantities, has placed the American diamond-cutters in a position equal to that held by those of Amsterdam, Antwerp, and Paris. The cutting of American gems has also assumed large proportions, notably in the cases of the beryls and amethysts of North Carolina and Connecticut, and of the turquoises, sapphires, tourmalines, chrysoprases, and garnets of other States.

THE Department of Agriculture and Technical Instruction for Ireland is publishing a series of Bulletins upon experimental science, and No. 4 of this series, relating to "Voltaic Electricity," has just been issued. It has been prepared by Mr. James Comerton, and is a useful little pamphlet of thirty pages with numerous illustrations. The author states in the introduction that the experiments described are merely intended to introduce the student to the more systematic study of electrical measurements. When the student has worked through the forty-three experiments described in this pamphlet, it is hoped that he will have a fair general working knowledge of voltaic electricity—its generation, measurements, and the purposes to which it can be applied. Primary cells, resistances, galvanometers, and voltameters are illustrated, and their use is described in these pages. The handbook should prove a useful addition to the literature of elementary electrical measurements.

THE principal centres of the calcium carbide industry in France are in the Alps and Pyrenees. At present, according to a writer in the *Journal of the Society of Arts*, there are eleven manufactories capable of producing 40,000 tons of calcium carbide annually. The total output sold during 1904 may be estimated at 18,000 tons. The average yield of gas per unit of weight of carbide is about 40 gallons per pound. The cost price per ton of calcium carbide in Europe was estimated by Prof. Lefevre, of the École des Sciences, Nantes, in 1897, at from 8*l*. to 10*l*. M. Pictet, however, in the same year, thought that the product might be made at the cost of a little more than 3*l*., by the use of a new furnace. Theoretically, said Prof. Lefevre, one pound of calcium carbide ought to produce, by its action upon water, about seven ounces of acetylene. It has been stated by one of the most important of the French firms, speaking of the production of 1904, that this was disposed of at 8*l*. per ton, the standard accepted and declared being about 40 gallons of gas per pound. The product at the factory realises 8*l*. per ton, and the rate for the retail dealer is 14*l*. These figures demonstrate the advances made in manufacturing since the publication of Prof. Lefevre's treatise in 1897.

PROF. D'ARSONVAL describes in the Bulletin of the French Physical Society a new and simple form of apparatus manufactured by the Société Française de l'Acétylène dissous, which serves for the generation and automatic compression of oxygen. The gas is generated by the combustion within the compression cylinder of a combustible substance mixed with potassium chlorate, the heat produced being sufficient to liberate the whole of the oxygen from the chlorate. The largest form of apparatus, the industrial type, gives a production of about 60 cubic feet of oxygen per hour. A new form of oxyacetylene burner is also described by means of which a very intense light is produced by allowing the jet to impinge upon a suitable mixture of the rare earths; lime and magnesia are useless for the purpose, as they are rapidly fused and channelled by the intense heat of the oxyacetylene flame.

DURING the past few years doubts have been expressed by several investigators, notably by Fitzgerald, Kahlenberg, Quincke, and Traube, of the correctness of Van 't Hoff's hypothesis that the osmotic pressure of solutions is purely a kinetic phenomenon due to the impact of the molecules of the solute against a membrane impermeable to them. This hypothesis has been so fertile of results and is so intimately associated with the progress of modern chemistry that any arguments of a subversive tendency have, generally speaking, received little attention. In a recent number of the *Atti dei Lincei* (vol. xiv., ii., p. 5) Prof. A. Battelli and A. Stefanini have brought forward, however, a number of facts which, if subsequently verified, are likely to prove insuperable objections to its validity. A necessary consequence of Van 't Hoff's hypothesis is that isosmotic solutions should, under similar conditions, be equimolecular; but it is stated that several cases have been observed in which solutions possessing very different molecular concentrations are in osmotic equilibrium. The characteristic of these solutions is that they have equal surface tensions, and it is contended that osmotic pressure is essentially a capillary phenomenon. Osmosis would then be a tendency to equalise the surface tensions of the liquids on the two sides of the membrane. The further developments of the authors' experiments will be watched with interest.

AN interesting lecture device for illustrating the superposition of simple harmonic motions of different periods has been submitted to us by Mr. W. C. Baker, of the School of Mining, Queen's University, Kingston, Ontario. A horizontal bar (about 4 cm. deep and 15 cm. long) carries a pointer about 50 cm. long rigidly attached to it. This system, which must be as light as possible, is suspended by two hinges which permit it to oscillate freely about a horizontal axis. To the underside of the bar are attached two pendulums (100 cm. and 75 cm. long) the bobs of which are of equal mass, say 250 grams each. If the pendulums be displaced together through an arc of, say, 15° and then released, the pointer will be set vibrating through an arc which will vary from a maximum when the pendulums are in phase with one another to very approximately zero when they are in opposition, thus illustrating the formation of beats. There is, of course, no obvious relation between the amplitude of the motion of the pointer and that of the pendulums; the oscillations of the latter give rise to periodic forces upon the horizontal bar, and the pointer indicates the resulting motion. We may point out that a somewhat analogous device was shown by Lord Rayleigh during a recent course of lectures at the Royal Institution.

Le Radium for August contains various articles and reviews on all the branches of radio-activity, together with a summary of current researches in this subject.

THE *Revue Scientifique* (September 9) contains an interesting summary on trypanosomes and trypanosomiasis by Dr. Brumpt. In addition to the ordinary pathogenic forms, the trypanosomes of birds, reptiles, and fishes receive notice.

ACCORDING to *La Nature* (September 16), the ravages of the phylloxera in northern Spain are very serious, many of the older vineyards being almost destroyed; and it is becoming a question whether it will not be necessary to substitute cereals and fruit for the vine in the affected districts.

THE *Bulletin of the Johns Hopkins Hospital* for September (xvi., No. 174) contains an interesting historical article on Cotton Mather's rules of health by Prof. William Thayer, together with papers of medical interest. Cotton Mather was a divine who was born in Boston in 1663, a learned man with a remarkable literary style, and his rules are often very quaint.

IN the August number of the *Journal of the Royal Microscopical Society*, Mr. Conrady writes on the application of the undulatory theory to optical problems, and

notes are contributed by Mr. Nelson on the presence of a flagellum at each end of the tubercle bacillus, by Lord Rayleigh on an optical paradox, and by Dr. Lazarus Barlow on a new form of hot stage. The usual summary of current researches concludes this excellent quarterly.

MESSRS. CHARLES GRIFFIN AND CO., LTD., have published a sixth edition of Mr. Andrew Jamieson's "Elementary Manual of Magnetism and Electricity." Several additions have been made in this new edition.

A KEY to the exercises in the second part of Mr. Pendlebury's "New School Arithmetic" has been prepared by the author and published by Messrs. George Bell and Sons. The price of the "Key" is 8*s.* 6*d.* net.

MESSRS. SMITH, ELDER AND CO. have published a sixth edition of Marshall and Hurst's "Junior Course of Practical Zoology." The new edition has been revised throughout by Dr. F. W. Gamble, who has also added short accounts of Monocystis, Coccidium, and Obelia.

THE following popular science lectures will be given at the Royal Victoria Hall, Waterloo Bridge Road, S.E., during next month:—October 3, "A Journey of Surprises: through Yunnan to Tonquin," Mrs. Archibald Little; October 10, "Smokeless Explosives," Mr. J. S. S. Brame; October 17, "The Plants of Other Days: what their Fruits and Seeds were Like," Mr. H. E. H. Smedley; October 24, "My Cruise Around Spain and Portugal," Mr. F. W. Gill.

MESSRS. PHILIP HARRIS AND CO., LTD., Birmingham, have just issued the third edition of their valuable catalogue of scientific instruments required in all departments of instruction or research in physics. The volume contains five hundred pages and is lavishly illustrated, a large number of the pictures representing new instruments or new methods of illustrating the principles of physical science. Many manuals and text-books of physics used in schools have been consulted, and novel forms of apparatus described in them are now made by Messrs. Harris, and appear in the present catalogue. The volume is well bound, and should be very useful for reference by teachers of physics in schools and colleges. No doubt it will find a permanent place on the bookshelves of many laboratories and lecture-rooms.

OUR ASTRONOMICAL COLUMN.

ASTRONOMICAL OCCURRENCES IN OCTOBER:—

Oct. 1. 8h. 52m. Minimum of Algol (β Persei).
„ 4. 5h. 41m. „ „ „
„ 8. 9h. Mars in conjunction with Uranus (Mars 1° 48′ S.).
„ 11. Saturn. Major axis of ring = 42″·28, Minor axis = 8″·46.
„ 14. 15h. Mars in conjunction with λ Sagittarii (mag. 2·9), Mars 0° 7′ N.
„ 15. Venus. Illuminated portion of disc = 0·868, of Mars = 0·861.
„ 19–22. Epoch of October meteoric shower (Radiant 92° + 15°).
„ 20. 6h. 51m. to 8h. 12m. Transit of Jupiter's Sat. III. (Ganymede).
„ 21. 10h. 35m. Minimum of Algol (β Persei).
„ 23. 18h. 24m. to 19h. 30m. Moon occults ρ Leonis (mag. 3·8).
„ 24. 7h. 23m. Minimum of Algol (β Persei).
„ 27. 10h. 15m. to 11h. 35m. Transit of Jupiter's Sat. III. (Ganymede).
„ 31. Uranus in conjunction with ι Sagittarii (mag. 5·3).

NOVA AQUILÆ.—Further news concerning Nova Aquilæ No. 2 is published in No. 4047 of the *Astronomische Nachrichten*. It appears that Mrs. Fleming discovered the existence of the Nova whilst examining the Draper memorial photographs on August 31. A photograph of the spectrum, taken on August 18, shows the hydrogen lines Hδ, Hγ, and Hβ bright and broad, also faint traces of the bright bands at λ 4472 and λ 4646. On that date the magnitude of the Nova was about 6·5, on August 21 it was 7·5, whilst on August 26 it had fallen to 10·0. No trace of the Nova is visible on a plate taken on August 10, although stars of magnitude 9·5 are shown thereon. A plate taken with the Bruce telescope at Arequipa on August 15, with an exposure of four hours, contains images of sixteenth-magnitude stars, but not of any object which can be recognised as the Nova.

A chart of the region, published by Prof. Wolf, shows the position of the Nova in regard to the star B.D. −4°.4663, and further shows that the Nova occupies a position between two spaces which are void of stars down to the fifteenth magnitude.

EPHEMERIS OF THE VARIABLE ASTEROID (167) URDA.—In No. 4047 of the *Astronomische Nachrichten* Herr A. Berberich publishes an ephemeris for the asteroid Urda, which Dr. Palisa recently showed to be variable.

The following is an extract from this ephemeris, which was calculated from the elements published in the "Jahrbuch" and for 12h. M.T. Berlin:—

1905	α (h. m. s.)	δ (° ′)	log r	log Δ
Sept. 28	22 13 18	−10 48·5		
Oct. 2	22 11 46	−11 0·3	0·4463	0·2875
„ 6	22 10 36	−11 9·9		
„ 10	22 9 49	−11 17·2	0·4467	0·3044

Observations made on August 31 and September 5 gave corrections to the above of +4s. and +0′·8.

The following figures indicate the changes of magnitude which were observed during the period July 30–September 5:—

Date	July 30	Aug. 31	Sept. 5
Magnitude	13·0	11·0	12·0

THE ULTRA-VIOLET CHROMOSPHERIC SPECTRUM.—At the total eclipse of 1900 M. H. Deslandres devoted his attention to two special researches, of which the first was to obtain the ultra-violet spectrum of the "reversing layer," and the second to obtain a great number of plates showing the bright lines, in order to detect the changes which might take place in the chromosphere in the interval between the second and third contacts.

In the first research he was successful, and obtained a duplicate series of plates showing the bright spectrum between λ 3000 and λ 5000. The first series was obtained with a prismatic camera of 1 metre focal length, the second with a camera of half this focal length. The prisms employed were of 60° angle, and were made of Iceland spar, whilst the objectives were made up of an achromatic combination of quartz and fluorspar.

The general results obtained from the reduction of one of the larger negatives, which was exposed for two seconds at second contact, are given in No. 9 (August 28) of the *Comptes rendus*, and deal only with the 157 lines photographed between λ 3400 and λ 3066. The chief characteristic of the spectrum in this region, as in the less refrangible region already known, is the predominance of "enhanced" titanium lines. In fact, M. Deslandres states that, considered as a whole, the spectrum is that of the titanium spark. Vanadium and chromium are represented by lines of less intensity, whilst the iron lines are extremely weak, the enhanced lines being considered in each case.

The coronal radiations are represented on two other negatives by well defined lines at $\lambda\lambda$ 3329.6, 3388.0, and 3447.7, the last having the greatest intensity. The same negatives, which were exposed for fifteen and thirty seconds respectively, show several prominences, and here, again, the spectrum of titanium predominates.

The "chronophotographe," an instrument for photographing from six to ten spectra per second at the two contacts, was less successful, the vibration produced by its manipulation spoiling the definition. M. Deslandres gives the details of the instrument, and points out its probable efficiency if suitably mounted.

THE FORMATION OF ICE AND THE GRAINED STRUCTURE OF GLACIERS.[1]

IN the following pages I have the honour to lay before the Royal Society the results of a lengthy research on the formation of ice and the grained structure of glaciers, which may serve as a complement to the previous investigations on the same subject published in the *Philosophical Transactions* and *Proceedings of the Royal Society* by Forbes, Tyndall and Huxley, Tyndall, Faraday, T. Graham, J. F. Main, J. C. McConnel, and D. A. Kidd, and elsewhere by Guyot, Agassiz, James Thomson, and Sir William Thomson (now Lord Kelvin), Hermann and Adolf Schlagintweit, Person, Leydolt, Rüdorff, Bertin, Grad, and A. Dupré, Moseley, A. Heim, J. T. Bottomley, K. R. Koch and Klocke, Forel, Ed. Hagenbach-Bischoff, E. von Drygalski, Mügge, H. Hess, and others.

(1) It will be convenient at the outset to define the precise meaning with which it is proposed to employ certain words, some of which are in vague popular use, while others are less familiar, or new.

By an *oily* liquid will be meant one which has surface tension in the common surface with other liquids with which it may be in contact. According to this definition a solution of any salt will, in comparison with pure water or a weaker salt solution, be called, in certain circumstances, an oily liquid.

An *emulsion* is a watery liquid containing suspended drops of oily liquid, or drops of any sort enclosed in an oily skin. These drops can coalesce into larger drops, or the oily skins can join on to one another, and form a continuous mass of bubbles, or foam. Thus *foam* consists of portions of watery liquid enclosed in, and separated from one another by adjacent partitions of oily liquid. Each space thus enclosed will be called a *foam-cell*, and the enclosing partition the foam-wall. If the foam-cells are very small, and the fluid foam-walls very thin (or invisible), the whole is then a *liquid jelly*. The jelly is stiff, the foam stiff or solid, when the walls or the contents of the foam-cells, or both, have become solid.

"*Nearly pure*" applied to water or ice will be used in the special sense of "containing only very small amounts of any salt." *Salt* itself is used throughout in the general chemical sense, that is, not restricted to sodium chloride.

(2) I have allowed pure water, and water containing dissolved salt, to freeze in the dark at various rates, and to melt away slowly in the dark, in open air, and in sunlight. The ice prisms employed were from 1 mm. to 1000 mm. thick, and as the thawing proceeded their various layers were systematically examined—sometimes for days together—with the naked eye, with the microscope, and with polarised light. The same appearances presented themselves in the same order as those which for thirty-seven years past I have investigated and described in solutions of silicic acid, glue, or other colloids, when these are evaporated to form gelatinous masses or thin films, and develop fissures. I have shown that thin viscous oily films of more concentrated solution exist in a less concentrated solution of the same substance, and form folds, straight and twisted tubes, cylinders or cones, spheres and bubbles, open and closed foam-cells with visible and invisible foam-walls. Thin solid films behave like films of very viscous liquid. Whether the oily films form tubes or bubbles and foam-cells joining on to one another depends on the viscosity of the oily liquid. The mutual inclination of the foam-walls, and their surface tensions, continually change as the concentration of the oily liquid changes, and in the case of invisible foam-walls may depend also on the thickness of the oily film. When the oily film is very thin, its surface tension diminishes with diminishing thickness of the film. Oily foam-walls that are formed against solid surfaces are normal to these surfaces. If three oily foam-walls meet in a common edge at equal angles of 120°, they have equal surface tensions.

The foam-cells of a liquid jelly immersed in water can increase or diminish in volume by the diffusion of water through the foam-wall inwards or outwards, *i.e.* the liquid jelly can *swell* or *shrink*. Two clots of liquid jelly can coalesce into one, which does not occur with clots of solid jelly, nor can these latter swell or shrink.

A liquid jelly becomes for the time being positively or negatively doubly refracting when the viscous walls, or the viscous contents of the foam-cells, are expanded or compressed. A jelly remains permanently doubly refracting when the walls or the contents of the foam-chambers solidify while in an expanded condition.

(3) Now, ice is a liquid jelly, with foam-walls of concentrated "oily" salt solution, which enclose foam-cells containing viscous, doubly refracting, pure or nearly pure water.

(4) The further the temperature falls below 0°, the greater is the viscosity of both liquids—in the walls and in the interior of the foam-cells—and the less the plasticity of the ice.

(5) At very low temperatures, the ice breaks with conchoidal fracture at the surface of the invisible spherical foam-walls, which as the whole cools have contracted differently from their contents.

(6) The "glacier grains" are foam-cells filled with pure or nearly pure ice, and separated from one another by visible or invisible walls of oily salt solution.

(7) The union of two pieces of ice under water ("regelation"), and the increase in size of the glacier grains as they approach the lower end of the glacier, correspond to the running together of two gelatinous clots (of silicic acid, or glue) containing liquid foam-cells and liquid cell-contents. At the same time the oily foam-walls between the glacier grains become thicker, and then get thinner again through the draining away of the liquid salt solution at the foot of the glacier.

(8) All water, even the purest, contains traces of salt. As the water cools, ice crystals and oily mother liquor separate at short intervals, or periodically. Under the influence of the surface tension, the oily salt solution forms invisible foam-walls, the surface-tension of which decreases as the thickness of the walls and the concentration of the salt solution diminish. Otherwise, as the cooling proceeds, the salt solution becomes continually more concentrated, and the wall thinner. Finally, the concentrated salt solution also freezes to ice and solid salt. The value of the surface tension determines the angles at which three walls meet in a common edge. If three foam-walls meet at equal angles of 120°, the three walls have equal surface tensions, whereas an inclination of 90° means that fluid foam-walls have been formed in contact with old and already solidified ones.

(9) When water containing air freezes, the air, like the salts dissolved in the water, separates out at short intervals, or periodically. The white places in ice, which are those containing these air bubbles, are also the richest in salt.

(10) As water containing salt, but free from air, cools, the periodical separation of ice and salt gives rise, alike in sea ice, in artificial ice, and in glacier ice, to layers of ice containing varying amounts of salt. By pressure or by absorption of radiation (sunlight, electric light, or daylight), the parts of the ice which are rich in salt melt sooner than pure ice.

(11) In sunlight or electric light furrows are formed at the places rich in salt on the surface of sea ice, artificial ice, and glacier ice. (Forel's stripes; Forbes's "dirt bands"; foam-walls of the great foam-cells of the Kjendal Glacier.)

(12) The salt solution formed in sea ice, artificial ice, or glacier ice, through pressure or sunshine, shows, by the hollows which it fills, the forms assumed under the influence of the surface tension by the boundary between the oily salt solution and the water, just before the freezing of the water. As the ice melts, it contracts. Thus in sea ice pressure or absorption of heat radiation causes the formation, in horizontal layers parallel to the frozen surface, of Tyndall's liquefaction figures, vacuous bubbles, ice flowers, and "fir trees" with branches meeting at 120° and 90°, just like those obtained when colloid solutions are evaporated to dryness, or when salt solutions are allowed to crystallise.

In the case of artificial ice which has been frozen in deep prismatic troughs, these liquefaction figures are formed in the diagonal and median planes of the ice block, which were the last parts to freeze, and where the mother liquor had accumulated.

[1] By Prof. G. Quincke, For.Mem.R.S. Paper received at the Royal Society on June 19.

(13) Sea ice and artificial ice break up in sunlight into little hexagonal prisms of clear ice. These suffer mutual displacement the less easily, the thinner are the fine foam-walls (which have now melted again, and which, when the freezing took place, were formed out of oily salt solution, normal to the surface), and the less salt the water contained before freezing.

The purer the water was, the larger are these hexagonal prisms or foam-cells.

(14) The capillary fissures in transparent glacier ice are these fine foam-walls of oily salt solution.

(15) When water containing little salt freezes in deep metal troughs surrounded with strongly cooled brine, the oily salt solution separates in thin layers normal to the surface, and forms bubbles, foam-cells clinging to one another, or—when the oily liquid at low temperatures is very viscous—folds or hollow pipes, which are filled with pure or nearly pure ice, or with air if such were present in the water. The artificial ice is seen to be traversed by many horizontal tubes, normal to the surface, which are specially numerous in the diagonal and median planes of the ice block, where the mother liquor had accumulated. The less salt is contained in the ice, the more transparent are these diagonal and median planes of the artificial ice block.

Illumination with sunlight or daylight causes the appearance of fresh tubes. The ice becomes more cloudy, and subsequently more transparent again.

(16) When water containing air freezes in deep metal troughs, the upper part of the ice block shows horizontal layers consisting alternately of transparent pure ice and of opaque salt-containing ice with numerous air bubbles. The more salt the water contains, the more numerous and the closer are the opaque layers. In sunlight these opaque layers melt more easily than the transparent ones, and furrows are formed on the surface of the opaque ice.

(17) If the ice is allowed to thaw again in a warm room, or is exposed to radiation (daylight), the parts rich in salt melt sooner than those which contain little salt. The tubes of oily salt solution bulge and coil up, and then break up with contraction of volume into spherical bubbles, which may be vacuous or filled with air. The foam-cells exhibit shapes like those of colloids and jellies as they swell or shrink, or those tree-like and branched formations which I have described in the case of the "liquid precipitates" of metallic silicates and cyanides. If the capillary fissures in this opaque ice are filled with very viscous salt solution, or if the oily salt solution forms no continuous foam-cells, it cannot run away. The ice remains white, as glacier ice actually does.

(18) When an ice block thaws under the long-continued action of daylight, there appear, in the diagonal and median planes of the block, bright bands and cloudy bands, which change their shape and position as the duration and intensity of the radiation alter. This is due to the formation of new foam-walls of oily salt solution and the disappearance of old ones. The angles between the foam-walls are also seen to change, which means that the surface tension of these walls is changing. Now as the amount of salt in the diagonal planes increases, and the absorbed radiation diminishes, towards the interior of the ice, and as further the surface tension and viscosity alter with changing concentration and temperature, it follows that the shapes assumed by the oily layers in the interior of the ice under the influence of the surface tension also undergo change.

(19) After thirty to thirty-six hours, the block of artificial ice had melted in the warm room to half its original height (1 metre), and at the foot and warmer places had given way in a pasty mass. In the upper portion, foam-walls had formed in the pure ice, inclined 120° to one another. In these, as in the median layer that had thawed away, melting salt solution ran down for hours. At the warmer places, and at the thin uppermost crust, glacier grains were formed. These were foam-cells, 5 mm. to 10 mm. wide, filled with doubly refracting ice, and separated from one another by singly refracting foam-walls of transparent salt solution. At the junctions of the foam-walls there often lay tetrahedra, bounded by spherical surfaces and filled with transparent liquid.

(20) In the diagonal and median planes of a block of artificial ice (1 metre high) containing a certain very small amount of salt, and exposed to a certain intensity of radiation, there can be formed horizontal closed tubes of pure or nearly pure ice, having rounded heads and sides bulging at places, and filled with liquid salt solution. They slowly swell, slowly break up into separate bubbles, and then slowly pass away. They are first formed low down, at places of high pressure, and afterwards higher up, at places of low pressure.

(21) When distilled water, free from air, was frozen in iron troughs, it was found at a certain temperature or with a certain concentration of the salt solution and the oily foam-wall that the walls and contents of the closed tubes in the lower part of the median plane were for some time coloured yellow. Subsequently this colour disappeared. It was not present when the water was frozen in brass troughs. I believe it was due to ferric oxide, which was differently soluble in the walls and in the liquid inside the foam-cells, and at a higher temperature became insoluble and sank to the bottom.

(22) The phenomena of melting ice depend both on the velocity of freezing and the velocity of thawing. The more rapidly the water freezes, the more numerous are the foam-walls, and the smaller the foam-cells.

(23) Very dilute solutions of different salts, when slowly frozen under similar conditions, give oily layers of varying viscosity and surface tension, or spheres, bubbles, tubes, and foam-walls of varying form. I have shown this with freshly boiled water containing 0·000003 per cent. of NaCl, or equivalent quantities of KCl, K_2CO_3, Na_2SO_4, $CaCl_2$, $MgCl_2$, $Al_2(SO_4)_3$. The water was frozen in prismatic troughs of brass or tin.

(24) During the freezing of water containing 0·0015 per cent. of Na_2SO_4, and also containing air, the air separated at the same time as the mother liquor. The bounding surface between air and almost solidified, very viscous liquid, tends to become as small as possible, and rolls up together to form hollow cylinders, the radii of which are the smaller the more quickly the ice has frozen. The water freezes the more slowly the further it is from the strongly cooled (below 0°) side of the trough. The thin layers forming the walls of the tubes are normal to the solid surface of the side of the trough, or of the transparent mantle of ice which encloses the mother liquor. They frequently form cylindrical or conical tubes, 6 mm. to 12 mm. long, with a whitish skin, and filled with air. Their axes are normal to the surface, and their pointed ends are directed towards the outer side of the ice mantle. At the base of the tubes, which may be 0·5 mm. to 2 mm. wide, there hangs a whitish hollow sphere inside the mother liquor.

(25) On slowly freezing water containing from 0·000014 per cent. to 0·0014 per cent. of Na_2SO_4, or 0·003 per cent. of NaCl, it happens at times that the mother liquor, which is surrounded by a transparent mantle of ice, contains numerous flat crystalline plates of pure ice. These, by their shape, position, and inclination to one another, clearly show that they have been formed from thin oily foam-walls of pure water, which, as the cooling proceeded, have separated from the watery salt solution, and then solidified.

(26) When a test tube, containing boiling distilled water, is plunged into liquid air, the water freezes very quickly to a milky-white mass of ice, with fissures normal to the surface of the glass. If the test-tube with the white ice—the whole being now cooled down to −190°—is plunged into distilled water, it becomes coated on the outside with a thin crust of ice, which can be detached with a knife, and examined in a watch-glass under the polarising microscope. It consists of small glacier grains or foam-cells (0·1 mm. to 0·2 mm. in diameter) the flat walls of which are normal to the cylindrical surface, and are inclined to one another at angles of 120°, 110°, and so on. The interior of each foam-cell contains a crystal of ice, which in the different cells is differently orientated. When the ice in the test-tube is crushed with a steel point, it exhibits a fibrous fracture, with fine fibres normal to the cylindrical surface. Occasionally in the cross-section are seen concentric cylinders composed alternately of transparent and of white ice. The latent heat of the slowly freezing water diminishes the loss of heat, and the velocity of cooling changes. The ice in the transparent layers was frozen

slowly, that in the opaque ones quickly. As this ice thaws in a watch-glass under the polarising microscope, the lumps of quickly frozen white ice exhibit immense numbers of strings—arranged radially alongside one another—of spheres and lenticular masses, 0·01 mm. to 0·02 mm. in thickness, consisting of very nearly pure water. In each sphere there was a vacuous bubble 0·0006 mm. in diameter.

(27) Slowly frozen water showed, on thawing, similar strings of (liquid) spheres and lenticular masses (of larger size, viz. 0·04 mm. to 0·12 mm. diameter), normal to the surface of the block of ice. These spheres and lens-shaped masses had been formed out of solid or hollow cylinders, or long thin cones with local swellings or bulgings. Frequently lens-shaped masses bounded by two spherical surfaces lay in a thin, flat, spiral or warped foam-wall.

(28) The fibres and cylindrical or conical tubes, like the tubes filled with air, were formed out of thin layers of very viscous, oily liquid, which, as the cooling proceeded, separated out, normal to the surface, and under the influence of the surface tension rolled up, being unable, by reason of excessive viscosity, to form spheres or bubbles.

(29) When the thawing has gone on for a long time, fewer foam-walls and larger foam-cells, or glacier grains, appear in the lumps of ice. The strings of liquid spheres, normal to the surface, show an increase in the size of the spheres, caused by the coalescence of the small spheres in the doubly refracting mass of ice into larger ones. An increased amount of salt in the ice assists this coalescence. The tubes or strings of spheres could often be followed continuously through several glacier grains. The partition walls of the glacier grains, when illuminated, often show hundreds of small lens-shaped masses of the same or gradually diminishing size.

(30) By repeated fractional freezing and melting of the ice crystals formed, continually purer and purer ice is obtained, with increasingly large foam-cells or glacier grains. I have, however, not yet succeeded, even by repeated slow freezing, in obtaining ice free from foam-walls or from glacier grains.

(31) A block of transparent ice was cut through, as described by Bottomley, with a loaded wire loop. The loop was of steel wire, or of platinum wire previously heated to redness, and carried 2 kilograms or more. In no case was the plane of section transparent, but always opaque from the presence of solidified foam bubbles of oily salt solution, possessing refracting power different from that of their surroundings.

(32) Each separate glacier grain in artificial ice contains a differently orientated crystal of ice, the optic axis of which is very seldom normal to the surface of the ice. When in natural sea ice the optic axes of the separate crystals in the different grains are found to be normal or parallel to the free surface of the water, the separation of orientated crystals of ice may have been started by the contact-action of ice crystals or snow flakes falling on the surface of the super-cooled water, and swimming thereon in a horizontal position.

(33) The more slowly artificial ice has frozen, and the less salt it contains, the more transparent, rigid, and difficult to cut with a knife it is.

(34) Every block of artificial ice cleaves, on pressure with a steel point, along the diagonal and median planes, in which, as the ice crystals separated out on freezing, the mother liquor became more concentrated through holding the traces of salt dissolved in a continually diminishing volume of liquid.

(35) The planes of easiest cleavage in natural ice crystals (laminated structure, displacement without bending) are due to invisible layers of liquid salt solution which are embedded in the crystals, normal to the optic axis, or often in other positions.

(36) Ice crystals at temperatures below 0° consist of doubly refracting viscous liquid, and are intermediate between the soft crystals of serum albumen and ordinary crystals of quartz, felspar, &c.

(37) At the edge of Tyndall's liquefaction figures, while they are in process of enlarging, or on the bursting of the foam-walls of artificial ice as it melts, one often sees periodic vortex movements. These arise from a periodic capillary spreading out ("Ausbreitung") of the salt solution of the foam-walls at the boundary between pure water and air or vacuum.

(38) Tyndall and Huxley observed in white glacier ice transparent lenticular masses bounded by spherical surfaces. These were foam bubbles of water free from air, which were enclosed in a thin skin of oily salt solution and had solidified while embedded in such a skin.

(39) The blue bands in glacier ice consist of pure ice, while the white bands are composed of ice containing salt and air bubbles. They are formed by the periodical action of solar radiation and by changing pressure, or by the slow descent of the portions rich in salt, or by the slow ascent of air bubbles in the viscous liquid of the glacier ice.

(40) The ice of the snow flakes which fall on the upper part of the glacier becomes fertilised with inorganic salts derived from disintegrated rocks, and is, as it were, hatched out by the sun's rays, forming "névé" or "firn" snow and glacier grains, or foam-cells filled with ice in the glacier proper. The glacier ice travels on, rolling (or "wallowing") slowly downwards as a living river of ice. Its skeleton of liquid salt solution changes the while, and forms new and larger foam-cells, which, at the lower end of the glacier, perish, disappear, and flow away as the water of the glacier stream.

THE BRITISH ASSOCIATION.

SECTION L.

EDUCATIONAL SCIENCE.

OPENING ADDRESS BY SIR RICHARD C. JEBB, LITT.D., D.C.L., M.P., PRESIDENT OF THE SECTION.

University Education and National Life.

EVERY country has educational problems of its own, intimately dependent on its social and economic conditions. The progressive study of education tends, indeed, towards a certain amount of general agreement on principles. But the crucial difficulties in framing and administering educational measures are very largely difficulties of detail; since an educational system, if it is to be workable, must be more or less accurately adjusted to all the complex circumstances of a given community. As one of those who are now visiting South Africa for the first time, I feel that what I bring with me from England is an interest in education, and some acquaintance with certain phases of it in the United Kingdom; but with regard to the inner nature of the educational questions which are now before this country, I am here to learn from those who can speak with knowledge. In this respect the British Association is doing for me very much what a famous bequest does for those young men whom it sends to Oxford; I am, in fact, a sort of Rhodes scholar from the other end—not subject, happily, to an age limit—who will find here a delightful and instructive opportunity of enlarging his outlook on the world, and more particularly on the field of education.

As usage prescribes that the work of this Section, as of others, should be opened by an Address from the Chair, I have ventured to take a subject suggested by one of the most striking phenomena of our time—the growing importance of that part which Universities seem destined to play in the life of nations.

Among the developments of British intellectual life which marked the Victorian age, none was more remarkable, and none is more important to-day, than the rapid extension of a demand for University education, and the great increase in the number of institutions which supply it. In the year 1832 Oxford and Cambridge were the only Universities south of the Tweed, and their position was then far from satisfactory. Their range of studies was too narrow; their social operation was too limited. Then, by successive reforms, the quality of their teaching was improved, and its scope greatly enlarged; their doors were opened to classes of the community against which they had formerly been closed. But meanwhile the growing desire for higher education—a result of the gradual improvement in elementary and secondary training—was creating new

institutions of various kinds. The earliest of these arose while access to Oxford and Cambridge was still restricted. The University of Durham was established in 1833. In 1836 the University of London, as an examining and degree-giving body, received its first charter. A series of important Colleges, giving education of a University type, arose in the greater towns of England and Wales. The next step was the formation of federal Universities. The Victoria University, in which the Colleges of Manchester, Liverpool and Leeds were associated, received its charter in 1880. The Colleges of Aberystwyth, Bangor, and Cardiff were federated in the University of Wales, which dates from 1893. The latest development has been the institution of the great urban Universities. The foundation of the University of Birmingham hastened an event which other causes had already prepared. The federal Victoria University has been replaced by three independent Universities, those of Manchester, Liverpool and Leeds. Lastly, a charter has recently been granted to the University of Sheffield. Then the University of London has been re-constituted; it is no longer only an Examining Board; it is also a teaching University, comprising a number of recognised schools in and around London. Thus in England and Wales there are now no fewer than ten teaching Universities. Among the newer institutions there are some varieties of type. But, so far as the new Universities in great cities are concerned, it may be said that they are predominantly scientific, and also that they devote special attention to the needs of practical life, professional, industrial and commercial; while at the same time they desire to maintain a high standard of general education. It may be observed that in some points these Universities have taken hints from the four ancient Universities of Scotland—which themselves have lately undergone a process of temperate reform. The Scottish Universities are accessible to every class of the community; and the success with which they have helped to mould the intellectual life of a people traditionally zealous for education renders their example instructive for the younger institutions. With reference to the provision made by the newer Universities for studies bearing on practical life, it should be remarked that much has been done in the same direction by the two older Universities also. At Cambridge, for example, degrees can be taken in Economics and associated branches of Political Science; in Mechanism and Applied Mechanics; and in Agricultural Sciences. It certainly cannot now be said that the old Universities neglect studies which are of direct utility, though they rightly insist that the basis and method of such studies shall be liberal.

In looking back on the general course of this whole movement in England, we find that it has been steady, smooth, and fairly rapid. It has not been due to any spasmodic impulse or artificial propaganda, but has been the result of natural forces operating throughout the nation. Universities, and the training which they give, have come to count for more in our national life as a whole. It should be noted in passing that the missionary movement known as University Extension did not arise in the first instance from spontaneous academic action, but was a response to public appeals from without. It had its origin in memorials addressed to the University of Cambridge, in 1872, by various public bodies; and it was in compliance with those memorials that, in the winter of 1873, the first courses of Extension lectures were organised in the Midlands. Another fact of vital significance in the movement is that it has included ample provision for the higher education of women.

With reference to the present position and prospects of the higher education in South Africa, I tried, before leaving England, to acquaint myself with at least the outlines of the general situation; but it is only with great diffidence that I shall offer a few observations bearing on some of the broader aspects of the question. I trust to be heard with indulgence by those from whom I shall hope to learn more. At any rate, I can truly say that the question seems to me one of the deepest interest and of the gravest importance. Indeed, it does not require much insight or imagination to apprehend the greatness of the issues that are involved.

In the first place, it would be correct, if I am not mistaken, to say that in South Africa at large there is a genuine and a keen desire for efficient education of the highest type. A sound liberal education is desired for all who can profit by it, whatever their future callings are to be. But the practical and immediate need for the organising of the highest teaching is felt, I believe, more particularly in regard to three great professions—the profession of Engineering, in all its branches; the profession of Agriculture (including Forestry); and the profession of Education itself, on which the intellectual future of South Africa must so largely and directly depend. That the interest in the higher instruction is so real must be regarded as the best tribute to the efforts of those able and devoted men who, in various parts of this land, have laboured with dauntless perseverance for the improvement of primary and secondary education. Unstinted gratitude is due also to the University of the Cape of Good Hope. It is acknowledged on all hands that the University, as the chief guardian of learning in South Africa, has done admirable work in maintaining a high standard of general education. Certainly it cannot be regarded as any disparagement of that work if, as seems to be the case, a widespread desire exists that South Africa should possess an institution, or institutions, of University rank, which, besides examining, should also teach. That is a natural progress, which is illustrated by the recent re-constitution of the London University itself. I am not qualified, nor should I desire, to discuss the various difficulties of detail which surround the question of a teaching University. That question is, for South Africa, an eminently practical one; and doubtless it will be solved, possibly at no distant time, by those who are most competent to deal with it. I will only venture to say a few words on some of the more general aspects of the matter.

The primary needs of daily life in a new country make demands for certain forms of higher training—demands which may be unable to wait for the development of anything so complex and costly as a teaching University. It is necessary to provide a training for men who shall be able to supervise the building of houses, the making of roads, bridges, and railways, and to direct skilled labour in various useful arts and handicrafts. The first step in such a provision is to establish technical schools and institutes. Germany is, I suppose, the country where the educational possibilities of the technical school are realised in the amplest measure. In Germany the results of the highest education are systematically brought to bear on all the greater industries. But this highest education is not given only in completely equipped Universities which confer degrees. It is largely given in the institutions known as Technical High Schools. In these schools teaching of a University standard is given, by professors of University rank, in subjects such as Architecture, various branches of Engineering, Chemistry, and General Technical Science. There are, I think, some ten or eleven of these Technical High Schools in Germany. In these institutions the teaching of the special art or science, on its theoretical side, is carried, I believe, to a point as high as could be attained in a University; while on the practical side it is carried beyond the point which in a University would usually be possible. In England we have nothing, I believe, which properly corresponds to the German Technical High School; but we may expect to see some of the functions of such a school included among the functions of the new Universities in our great industrial and commercial towns.

Now Technical Schools or Institutes, which do not reach the level of a German Technical High School, may nevertheless be so planned as to be capable of being further developed as parts of a great teaching University. And the point which I now wish to note is this—that the higher education given in a Technical Institute, which is only such, will not be quite the same as that given in the corresponding department of a teaching University. University education, as such, when it is efficient, has certain characteristics which differentiate it from the training of a specialist, however high the level of the teaching in the special subject may be. Here, however, I pause for a moment to guard against a possible misconception. I am

not suggesting that the specialist training given in a technical institute, though limited, is not an excellent thing in itself; or that, in certain conditions and circumstances, it is not desirable to have such a training, attested by a diploma or certificate, instead of aiming at a University standard and a University degree. Universities themselves recognise this fact. They reserve their degrees for those who have had a University training; but they also grant diplomas for proficiency in certain special branches of knowledge. Cambridge, for instance, gives a diploma in the Science and Practice of Agriculture; and the examinations for the diploma are open to persons who are not members of the University.

But the University training, whatever its subject, ought to give something which the purely specialist training does not give. What do we understand by a University education? What are its distinctive characteristics? The word *Universitas*, as you know, is merely a general term for a corporation, specially applied in the Middle Ages to a body of persons associated for purposes of study, who, by becoming a corporation, acquired certain immunities and privileges. Though a particular University might be strongest in a particular faculty, as Bologna was in Law and Paris in Theology, yet it is a traditional attribute of such a body that several different branches of higher study shall be represented in it. It is among the distinctive advantages of a University that it brings together in one place students—by whom I mean teachers as well as learners—of various subjects. By doing this the University tends to produce a general breadth of intellectual interests and sympathies; it enables the specialist to acquire some sense of the relations between his own pursuit and other pursuits; he is helped to perceive the largeness of knowledge. But, besides bringing together students of various subjects, it is the business of a University to see that each subject shall be studied in such a manner as to afford some general discipline of the mental faculties. In his book on "The Idea of a University" Newman says:—

"This process of training, by which the intellect, instead of being formed or sacrificed to some particular or accidental purpose, some specific trade or profession, or study or science, is disciplined for its own sake, for the perception of its own proper object, and for its own highest culture, is called Liberal Education; and though there is no one in whom it is carried as far as is conceivable, or whose intellect would be a pattern of what intellects should be made, yet there is scarcely anyone but may gain an idea of what real training is, and at least look towards it, and make its true scope and result, not something else, his standard of excellence; and numbers there are who may submit themselves to it and secure it to themselves in good measure. And to set forth the right standard, and to train according to it, and to help forward all students towards it according to their various capacities, this I conceive to be the business of a University."

It may be granted that the function of a University, as Newman here describes it, is not always realised; Universities, like other human institutions, have their failures. But his words truly express the aim and tendency of the best University teaching. It belongs to the spirit of such teaching that it should nourish and sustain ideals; and a University can do nothing better for its sons than that; a vision of the ideal can guard monotony of work from becoming monotony of life. But there is yet another element of University training which must not be left out of account; it is, indeed, among the most vital of all. I mean that informal education which young men give to each other. Many of us, probably, in looking back on our undergraduate days, could say that the society of our contemporaries was not the least powerful of the educational influences which we experienced. The social life of the Colleges at Oxford and Cambridge is a most essential part of the training received there. In considering the questions of the higher education in South Africa it is well to remember that the social intercourse of young students, under conditions such as a great residential University might provide, is an instrument of education which nothing else can replace. And it might be added that such social intercourse is also an excellent thing for the teachers.

The highest education, when it bears its proper fruit, gives not knowledge only, but mental culture. A man may be learned, and yet deficient in culture; that fact is implied by the word "pedantry." "Culture," said Huxley, "certainly means something quite different from learning or technical skill. It implies the possession of an ideal, and the habit of critically estimating the value of things by a theoretic standard." "It is the love of knowledge," says Henry Sidgwick, "the ardour of scientific curiosity, driving us continually to absorb new facts and ideas, to make them our own, and fit them into the living and growing system of our thought; and the trained faculty of doing this, the alert and supple intelligence exercised and continually developed in doing this—it is in these that culture essentially lies." And if this is what culture really means, evidently it cannot be regarded as something superfine—as an intellectual luxury suited only for people who can lead lives of elegant leisure. Education consists in organising the resources of the human being; it seeks to give him powers which shall fit him for his social and physical world. One mark of an uneducated person is that he is embarrassed by any situation to which he is not accustomed. The educated person is able to deal with circumstances in which he has never been placed before; he is so, because he has acquired general conceptions; his imagination, his judgment, his powers of intelligent sympathy have been developed. The mental culture which includes such attributes is of inestimable value in the practical work of life, and especially in work of a pioneer kind. It is precisely in a country which presents new problems, where novel difficulties of all sorts have to be faced, where social and political questions assume complex forms for which experience furnishes no exact parallels, it is precisely there that the largest and best gifts which the higher education can confer are most urgently demanded.

But how is culture, as distinct from mere knowledge, to be attained? The question arises as soon as we turn from the machinery of the higher education to consider its essence, and the general aims which it has in view. Culture cannot be secured by planning courses of study, nor can it be adequately tested by the most ingenious system of examinations. But it would be generally allowed that a University training, if it is really successful, ought to result in giving culture, over and above such knowledge as the student may acquire in his particular branch or branches of study. We all know what Matthew Arnold did, a generation ago, to interpret and diffuse in England his conception of culture. The charm, the humour, and also the earnestness of the essays in which he pleaded that cause render them permanently attractive in themselves, while at the same time they have the historical interest of marking a phase in the progress of English thought and feeling about education. For, indeed, whatever may be the criticisms to which Arnold's treatment of the subject is open in detail, he truly indicated a great national defect; and by leading a multitude of educated persons to realise it, he helped to prepare the way for better things. Dealing with England as it was in the 'sixties, he complained that the bulk of the well-to-do classes were devoid of mental culture—crude in their perceptions, insensible to beauty, and complacently impenetrable to ideas. If, during the last thirty or forty years, there has been a marked improvement, the popular influence of Matthew Arnold's writings may fairly be numbered among the contributory causes, though other and much more potent causes have also been at work. When we examine Arnold's own conception of culture, as expressed in successive essays, we find that it goes through a process of evolution. At first he means by "culture" a knowledge and love of the best literature, ancient and modern, and the influence on mind and manners which flows thence. Then his conception of culture becomes enlarged; it is now no longer solely or mainly æsthetic, but also intellectual; it includes receptivity of new ideas; it is even the passion for "seeing things as they really are." But there is yet a further development. True culture, in his final view, is not only æsthetic and intellectual; it is also moral and spiritual; its aim is, in his

phrase, "the harmonious expansion of all the powers which make the beauty and worth of human nature." But whether the scope which Arnold, at a particular moment, assigned to culture was narrower or wider, the instrument of culture with which he was chiefly concerned was always literature. Culture requires us, he said, to know ourselves and the world; and, as a means to this end, we must "know the best that has been thought and said in the world." By literature, then—as he once said in reply to Huxley—he did not mean merely *belles lettres*; he included the books which record the great results of science. But he insisted mainly on the best poetry and the highest eloquence. In comparing science and literature as general instruments of education, Arnold observed that the power of intellect and knowledge is not the only one that goes to the building-up of human life; there is also the power of conduct and the power of beauty. Literature, he said, serves to bring knowledge into relation with our sense for conduct and our sense for beauty. The greater and more fruitful is the progress of science, the greater is the need for humane letters, to establish and maintain a harmony between the new knowledge and those profound, unchanging instincts of our nature.

It is not surprising that, in the last third of the nineteenth century, Arnold's fascinating advocacy of literature, as the paramount agency of culture, should have incurred some criticism from the standpoint of science and of philosophy. The general drift of this criticism was that the claim which he made for literature, though just in many respects, was carried too far; and also that his conception of intellectual culture was inadequate. As a representative of such criticism, I would take the eminent philosopher whose own definition of culture has already been cited, Henry Sidgwick: for no one, I think, could put more incisively the particular point with which we are here concerned. "Matthew Arnold's method of seeking truth," says Sidgwick, "is a survival from a pre-scientific age. He is a man of letters pure and simple; and often seems quite serenely unconscious of the intellectual limitations of his type." The critic proceeds to enumerate some things which, as he affirms, are "quite alien to the habitual thought of a mere man of letters." They are such as these: "How the crude matter of common experience is reduced to the order and system which constitutes it an object of scientific knowledge; how the precisest possible conceptions are applied in the exact apprehension and analysis of facts, and how by facts thus established and analysed the conceptions in their turn are gradually rectified; how the laws of Nature are ascertained by the combined processes of induction and deduction, provisional assumption and careful verification; how a general hypothesis is used to guide inquiry, and, after due comparison with ascertained particulars, becomes an accepted theory; and how a theory, receiving further confirmation, takes its place finally as an organic part of a vast, living, ever-growing system of knowledge." Sidgwick's conclusion is as follows: "Intellectual culture, at the end of the nineteenth century, must include as its most essential element a scientific habit of mind; and a scientific habit of mind can only be acquired by the methodical study of some part at least of what the human race has come scientifically to know."

There is nothing in that statement to which exception need be taken by the firmest believer in the value of literary education. The more serious and methodical studies of literature demand, in some measure, a scientific habit of mind, in the largest sense of that expression; such a habit is necessary, for instance, in the study of history, in the scientific study of language, and in the "higher criticism." Nor, again, does anyone question that the studies of the natural sciences are instruments of intellectual culture of the highest order. The powers of observation and of reasoning are thereby disciplined in manifold ways; and the scientific habit of mind so formed is in itself an education. To define and describe the modes in which that discipline operates on the mind is a task for the man of science; it could not, of course, be attempted by anyone whose own training has been wholly literary. But there is one fact which may be noted by any intelligent observer. Many of our most eminent teachers of science, and more especially of science in its technical applications, insist on a demand which, in the province of science, is analogous to a demand made in the province of literary study by those who wish such study to be a true instrument of culture. As the latter desire that literature should be a means of educating the student's intelligence and sympathies, so the teachers of science, whether pure or applied, insist on the necessity of cultivating the scientific imagination, of developing a power of initiative in the learner, and of drawing out his inventive faculties. They urge that, in the interests of the technical industries themselves, the great need is for a training which shall be more than technical—which shall be thoroughly scientific. Wherever scientific and technical education attains its highest forms in institutions of University rank, the aim is not merely to form skilled craftsmen, but to produce men who can contribute to the advance of their respective sciences and arts, men who can originate and invent. There is a vast world-competition in scientific progress, on which industrial and commercial progress must ultimately depend; and it is of national importance for every country that it should have men who are not merely expert in things already known, but who can take their places in the forefront of the onward march.

But meanwhile the claims of literary culture, as part of the general higher education, must not be neglected or undervalued. It may be that, in the pre-scientific age, those claims were occasionally stated in a somewhat exaggerated or one-sided manner. But it remains as true as ever that literary studies form an indispensable element of a really liberal education. And the educational value of good literature is all the greater in our day, because the progress of knowledge more and more enforces early specialisation. Good literature tends to preserve the breadth and variety of intellectual interests. It also tends to cultivate the sympathies; it exerts a humanising influence by the clear and beautiful expression of noble thoughts and sentiments; by the contemplation of great actions and great characters; by following the varied development of human life, not only as an evolution governed by certain laws, but also as a drama full of interests which intimately concern us. Moreover, as has well been said, if literature be viewed as one of the fine arts, it is found to be the most altruistic of them all, since it can educate a sensibility for other forms of beauty besides its own. The genius of a Ruskin can quicken our feeling for masterpieces of architecture, sculpture, and painting. Even a very limited study of literature, if it be only of the right quality, may provide permanent springs of refreshment for those whose principal studies and occupations are other than literary. We may recall here some weighty words written by one of the very greatest of modern men of science. "If I had to live my life again," said Charles Darwin, "I would have made it a rule to read some poetry and listen to some music at least once every week. . . . The loss of these tastes is a loss of happiness, and may possibly be injurious to the intellect, and more probably to the moral character, by enfeebling the emotional part of our nature." The same lesson is enforced by John Stuart Mill, in that remarkable passage of his Autobiography where he describes how, while still a youth, he became aware of a serious defect, a great lacuna, in that severe intellectual training which, for him, had commenced in childhood. It was a training from which the influences of imaginative literature had been rigidly excluded. He turned to that literature for mental relief, and found what he wanted in the poetry of Wordsworth. "I had now learned by experience"—this is his comment—"that the passive susceptibilities needed to be cultivated as well as the active capacities, and required to be nourished and enriched as well as guided." Nor is it merely to the happiness and mental well-being of the individual that literature can minister. By rendering his intelligence more flexible, by deepening his humanity, by increasing his power of comprehending others, by fostering worthy ideals, it will add something to his capacity for cooperating with his fellows in every station of life and in every phase of action; it will make him a better citizen, and not only a more sympathetic but also a more efficient member of society.

One of the urgent problems of the higher education in our day is how to secure an adequate measure of literary culture to those students whose primary concern is with scientific and technical pursuits. Some of the younger English Universities, which give degrees in Science, contribute to this purpose by providing certain options in the Science curriculum; that is, a given number of scientific subjects being prescribed for study with a view to the degree of B.Sc., the candidate is allowed to substitute for one of these a subject taken from the Arts curriculum, such, for instance, as the Theory and Practice of Education. This is the case in the University of Wales and in the University of Birmingham; and there are indications, I believe, that this example will be followed elsewhere. Considering how hard and sustained is the work exacted from students of science, pure or applied, it seems important that the subjects from which they are to derive their literary culture should be presented to them, not in a dryasdust fashion, not chiefly as subjects of examination, but rather as sources of recreation and changes of mental activity. From this point of view, for British students of science the best literature of the English language offers unequalled advantages. It may be mentioned that the Board of Education in London is giving particular attention to the place which English literature should hold in the examination of students at the Training Colleges, and has under consideration carefully planned courses of study, in which portions of the best English writers of prose and of verse are prescribed to be read in connection with corresponding periods of English history, it being understood that the study of the literature shall be directed, not to philological or grammatical detail, but to the substance and meaning of the books, and to the leading characteristics of each writer's style. If, on the other hand, the student is to derive his literary culture, wholly or in part, from a foreign literature, ancient or modern, then it will be most desirable that, before leaving school, he should have surmounted the initial difficulties of grammar, and should have learned to read the foreign language with tolerable ease.

When we look at this problem—how to combine the scientific and the literary elements of culture—in the light of existing or prospective conditions in South Africa, it appears natural to suppose that, in a teaching University, the Faculty of Education would be that with which literary studies would be more particularly connected. And if students of practical sciences, such as Engineering and Agriculture, were brought together at the same centre where the Faculty of Education had its seat, then it should not be difficult, without unduly trenching on the time demanded by scientific or technical studies, to provide such students with facilities for some measure of good literary training.

A further subject is necessarily suggested by that with which we have been dealing—I mean the relation of University to Secondary Education; but on that I can only touch very briefly. Before University Education can be widely efficient, it is indispensable that Secondary Education should be fairly well developed and organised. Secondary Education should be intelligent—liberal in spirit—not too much trammelled by the somewhat mechanical uniformity apt to result from working for external examinations, but sufficiently elastic to allow for different aptitudes in the pupils, and to afford scope for the free initiative of able teachers. It is a gain for the continuity of education when a school-leaving examination can be accepted as giving admission to the University. Such an examination must be conducted under the authority of the University; but there is much to be said in favour of the view that, under proper safeguards, the school-teachers should have a part in the examination; always provided that the ultimate control, and the decision in all cases of doubt, shall rest with the University. A system of school-leaving examinations for this country was earnestly advocated, I believe, by Mr. P. A. Barnett, who has achieved such excellent work for the cause of education in Natal. To discuss the advantages or difficulties of such a proposal, as they at present affect South Africa, would demand knowledge which I do not possess; and I must content myself with the expression of a hope that in days to come—perhaps in a not distant future—it may be found practicable to form such a link between the highest education and the grade next below it.

But the limit of time proper for a Chairman's address has now almost been reached. I thank you sincerely for the kindness and patience with which you have heard me. In conclusion, I would only say how entirely I share a conviction which has been expressed by one to whose ability, to whose generous enthusiasm and unflagging efforts the cause of education in this country owes an incalculable debt—I refer to Mr. E. B. Sargant. Like him, I believe that the progress of education in all its grades, from the lowest to the highest, is the agency which, more surely than any other, will conduce to the prosperity and the unity of South Africa. For all workers in that great cause it must be an inspiring thought that they are engaged in promoting the most fundamental and the most far-reaching of national interests. They are endeavouring to secure that the men and women to whom the future of this country belongs shall be equal to their responsibilities and worthy of their inheritance. In that endeavour the sympathies which they carry with them are world-wide. As we come to see, more and more clearly, that the highest education is not only a national but an Imperial concern, there is a growing desire for interchange of counsels and for active cooperation between the educational institutions of the Colonies and those of the Mother Country. The development of education in South Africa will command keen attention, and will be followed by earnest good wishes, not only in England but throughout the British dominions. One of the ideas which are bound up with the history and the traditions of our English public schools and Universities is the idea of efficient work for the State. Those institutions have been largely moulded, from generation to generation, by the aim of ensuring a supply of men qualified to bear a worthy part, either in the government of the nation, or in professional activities which are indispensable to the national welfare. In our own time, and more especially within the last thirty years, one particular aspect of that idea is illustrated by the closer connections which have been formed between the Universities and the higher branches of the Civil Service. The conception of work for the commonweal is in its turn inseparable from loyalty to those ideals of character and conduct by which English life and public policy have been built up. It is by the long and gradual training which such ideals have given that our race has been fitted to grapple with responsibilities which have inevitably grown, both in extent and in complexity, far beyond anything of which our forefathers could have dreamed. That training tends also to national self-knowledge; it makes for a sober estimate of our national qualities and defects; it quickens a national sense of duty to our neighbour. The munificence of a far-sighted statesman has provided that selected youths, whose homes are in this land, and whose life-work may be here, shall go for a while to England, shall breathe the intellectual and social atmosphere of a great English University, and shall learn to judge for themselves of the sources from which the best English traditions have flowed. That is excellent. But it is also most desirable that those traditions should pass as living forces into the higher teaching of South Africa itself, and that their spirit should animate educational institutions the special forms of which have been moulded by local requirements. That, indeed, has been, and is, the fervent wish of men whose labours for South African education have already borne abundant fruit, and are destined to bear yet larger fruit in the future. May those labours prosper, and may that wish be fulfilled! The sooner will come the day when the inhabitants of this country, this country of vast and still indefinite possibilities, will be able to feel, in a sense higher and deeper than citizens of the Roman Empire could conceive, *Cuncti gens una sumus* ("We are all one people"). If the work which lies before us, in this Section of the British Association, should result in contributing anything towards the promotion of those great objects, by helping to elucidate the conditions of further progress, our deliberations will not have been held in vain.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

THE Goldsmiths' College, New Cross, the gift of the Goldsmiths' Company to the University of London, will be opened to-morrow, September 29, by the Earl of Rosebery, K.G., K.T., F.R.S.

ON October 5 Prof. J. W. Judd, C.B., F.R.S., will distribute the medals, prizes, &c., gained by the students of the Royal College of Science. The distribution will take place in the lecture theatre of the Victoria and Albert Museum, South Kensington, at 4 p.m.

THE University of Wisconsin has established a course in chemical engineering. Besides the regular professorial instruction, arrangements have been made for occasional lectures by prominent engineers. The course, which covers four years, includes gas engineering and electrolytic work, as well as other branches of chemical practice.

CONSEQUENT upon the closing of Coopers Hill College, it has been decided that probationers for the Indian Forest Department will take their theoretical course at Oxford. The writer of an article in the *Indian Forester* (July) on the future training of the upper staff of the Indian Forest Department recognises several advantages in the change. But while approval is expressed with the nature of the theoretical course and the experience that will be gained at Oxford, it is pointed out that a practical course in India, as, for instance, at Dehra Dun, would afford greater scope and provide more useful training for the work that is required of Indian forest officers than sending candidates to study forestry practice on the Continent.

THE French and Prussian Governments have recently established a system under which a number of young masters in English secondary schools may be attached for a year to certain secondary schools in their respective countries. The authorities of the foreign Ministries of Public Instruction are most anxious to extend the scheme and to find similar opportunities in suitable English secondary schools for young graduates who will afterwards be employed in their State schools. In the opinion of the Board of Education, the proposal has much to recommend it, and, provided that proper care be exercised in the selection of the candidates and in the arrangements made for their work, it is thought that the presence of such teachers on the staff of a school would add materially to the effectiveness of the modern language teaching. Headmasters who are willing to cooperate and to employ such assistants are requested to communicate with the Director of Special Inquiries and Reports, Board of Education Library, St. Stephen's House, Cannon Row, Westminster, S.W.

THE following free public introductory lectures will be delivered at University College, London, during October. Sir William Ramsay, K.C.B., F.R.S., will lecture on some advances in chemistry; Prof. L. M. Brandin on 'la critique littéraire au xix[e] siècle"; Prof. L. W. Lyde on the teaching of geography to children; Prof. H. S. Foxwell on some aspects of competition in modern business; Prof. F. Mackarness on the origins of Roman Dutch law and its introduction into the British Empire; Prof. E. A. Gardner on architectural sculptures; and Sir John Macdonell on some present directions in legislation. In the department of chemistry of the college several courses of work have been arranged for the ensuing session, viz. Sir William Ramsay, K.C.B., F.R.S., will lecture on the inactive gases of the atmosphere, and on the physics and chemistry of colours; Mr. E. C. Baly will give a course of lectures on spectroscopy and spectrum photography; Mr. J. H. K. Inglis one on recent advances in inorganic chemistry; and Mr. N. T. M. Wilsmore one on electrochemistry. A laboratory course in experimental psychology, consisting of lectures and practical demonstrations, will be given by Mr. W. McDougall, and a course of about thirty lectures on advanced psychology will be delivered by Prof. G. Dawes Hicks. Six lectures, open to the public without payment or ticket, will be given during November by Mr. G. U. Yule on the vital statistics of England and Wales.

THE Marquis of Linlithgow, Secretary for Scotland and vice-president of the Committee of Council on Education in Scotland, is to open the Dunfermline College of Hygiene and Physical Training on Wednesday next, October 4. A correspondent writing to the *Times* says that the establishment of a college of hygiene may be described as an afterthought on the part of the Carnegie trust. When the palatial gymnasium and baths, given to his native city by Mr. Carnegie at a cost of about 40,000*l.*, was approaching completion it attracted the notice of the highest educational a[illegible] in Scotland, who recognised the fitness of the building, with its splendid equipments, to supply what they considered a serious defect in the national provision for education, viz. the instruction of teachers in physical training. After careful consideration the Carnegie trustees, who have charge of the building, agreed to entertain the appeal of the experts to link the local benefaction, of which they are the administrators, with a national service which, while bringing additional distinction to the city, would ensure greater efficiency in the physical training supplied to the local schools. The lady superintendent of athletic instruction has been transformed into the principal of the physical training college, a residence for women students has been acquired, a medical officer has been appointed to devote his whole time to the work of the college, and a course of study has been marked out to extend over two years and to include hygiene, anatomy, physiology, educational and remedial gymnastics on the Swedish system, games, swimming, dancing, &c.

SIR DONALD CURRIE'S letter to the president of Queen's College, Belfast, offering a sum of money under certain conditions for the better equipment of the college was submitted at a private meeting of the executive committee of the college fund on September 22. It was unanimously resolved to convey to Sir Donald Currie the thanks of the committee for his proposal. It was also resolved that in view of the munificent offer of Sir Donald Currie, the committee earnestly appeal to all old students of the college and all who are interested in the promotion of education in Belfast and Ulster to assist in raising the required sum of 20,000*l.* before Christmas. The Rev. Dr. Hamilton, president of Queen's College, writing to the Belfast papers on September 23 in reference to Sir Donald Currie's offer of 20,000*l.*, says that for some time Queen's College has been engaged in a strenuous effort to better its equipments, so as to bring them into line with the scientific and educational advances of our time and with its own growth and development in recent years. This enterprise was inaugurated four years ago, and, notwithstanding adverse circumstances, quickly attained a gratifying success. A sum of more than 30,000*l.* has been raised, by means of which most important additions have been made to the working power of the college. One laboratory has been built and equipped, and the foundation of a second will, it is hoped, be laid before many weeks have passed. If the college succeeds in satisfying the reasonable conditions which Sir Donald Currie lays down, the fund will be increased to 70,000*l.*, and the college will be placed in a financial position such as it never before occupied.

AMONG the calendars and educational directories published during the past few days we notice those of the Northampton Institute at Clerkenwell, the Armstrong College at Newcastle-upon-Tyne, and the Plymouth Education Authority. At the Northampton Institute the following classes are worthy of mention, viz. the day and evening courses in mechanical and electrical engineering, in technical optics, and in horology. In addition to these there are evening courses in technical chemistry and i domestic economy. The Armstrong College was former known as the Durham College of Science. The colle forms an important part of the University of the Nor of England, and the degrees of Durham in science and letters, and its diplomas in engineering, are open students of this Newcastle institution. It may be no that, in addition to the biological laboratories at college, a marine biological laboratory has been at Cullercoats, and by the generosity of the North land Sea Fisheries Committee is available for st The agricultural department has been entrusted

scientific direction of the farm acquired for the purpose of experiment and demonstration by the Northumberland County Council. The new calendar contains full information of all the courses of work arranged for the coming session. The Plymouth directory contains an excellent diagram showing in a graphic manner the arrangements made by the local education authority to coordinate the work in all Plymouth schools. The classes at the school of science and technology make it possible for any workman anxious to acquaint himself with the scientific principles of his calling to do so easily.

In order to facilitate the adoption by secondary schools of systematic courses in geography, the Board of Education has issued a circular indicating in outline the points to which the attention of inspectors will be directed when inspecting classes in this subject. Each school desiring the approval of the Board for its course in geography should be prepared to submit a course providing, first, an outline scheme dealing with the great land and water areas in such a way that on completing the course the pupils shall have gone through the geography of the world; and, secondly, a suitably graded series of exercises connected with the subjects included in the course. The Board lays it down that the aim of the teaching should be to produce a vivid impression of connected facts through considerations, such as those of cause and effect, and the practical bearings of the facts selected. Referring to the exercises, the circular states that these may consist of (a) questions and answers designed to elicit, through causes and consequences, subject-matter for entry in the pupils' note-books; (b) notes and diagrams which should include worked-out problems together with original maps and plans; (c) mapping; and (d) field work, excursions, factory visits, &c. Suggestions for a four-year course in geography, together with an outline plan for preliminary instruction, are also given. The work suggested for the preliminary instruction as suitable for children from eight to twelve, and the statement of what these pupils should be expected to know before entering upon the four-years' course, presume a standard of attainment which the Board can scarcely expect to be realised at present. The knowledge of physiography, for instance, to be expected of these young people would be a credit to students several years older. As so few teachers of geography understand what is meant by the scientific study of their subject, it would have been an advantage if the instructions as to the practical work to be done could have been made more explicit. The circular refers to "worked-out problems," but it might with advantage have included a few typical examples of the problems required. The real difficulty will be to find teachers capable of acting in the spirit of the suggestions made by the Board; but it is something for them to have a method indicated which not only is sound in principle, but is being put into practice here and there. The circular is a decided step in advance, and brings nearer the time when scientific instruction in geography will be general in schools of all grades.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, June 8.—"The Pharmacology of Indaconitine and Bikhaconitine." By Dr. J. Theodore **Cash,** F.R.S., and Prof. Wyndham R. **Dunstan,** F.R.S.

The present paper deals with the physiological action of two new "aconitines," which have been isolated at the Imperial Institute from two varieties of Indian aconite. One is an alkaloid, which has been named indaconitine. It was found in the roots of the Indian aconite, called by Bruhl *Aconitum napellus*, var. *hians*, since identified by Stapf as a new species which has received the name of *Aconitum chasmanthum*. The other alkaloid has been named "bikhaconitine," being derived from one of the highly poisonous forms of aconite known in India under the vernacular name of "Bikh." This aconite was named by Bruhl *Aconitum ferox*, var. *spicatum*, but has been renamed *Aconitum spicatum* by Stapf, who regards it as a distinct species.

Results of experiments with these two substances are summarised as follows:—

The two aconitines, indaconitine and bikhaconitine, agree in their qualitative effects with the other alkaloids of this series, aconitine, japaconitine, and pseudaconitine, which have been dealt with in our previous papers.

The toxicity of indaconitine is less than that of bikhaconitine towards warm-blooded animals; in this respect the former stands very near to the aconitine of *A. napellus*, whilst the latter, being somewhat stronger than japaconitine, is to be referred to a position between this alkaloid and pseudaconitine from forms of *A. ferox*, which is much the most active of the series.

The depression of the respiratory function by indaconitine is less than that produced by bikhaconitine, and to this the greater toxicity of the latter is referable. Repeated doses of alkaloids administered at regular intervals and in similar fractional proportions of the lethal dose are followed by a more marked toxic effect when bikhaconitine is administered rather than indaconitine. Towards frogs the toxicity of the two alkaloids under discussion is practically equal; bikhaconitine is more active than indaconitine in reducing the respiratory activity. On the other hand, it is somewhat less active in abolishing the excitability of muscular and intramuscular motor nervous tissue (immersion experiments), and in reducing the ability of the muscle-nerve preparation poisoned *in situ* for the performance of work sufficient to cause fatigue. The local effect of the two aconitines when applied to the skin by inunction is equal and similar to that of the aconitines already considered.

Indaconitine and bikhaconitine may therefore be substituted for aconitine and pseudaconitine for internal use, indaconitine being administrable in the same dose as aconitine (from *A. napellus*) and bikhaconitine in proportion of 0·75 of the unit dose of the former, whilst for local application they may be used as constituents of ointments in similar proportions to aconitine.

Pseudaconine from Pseudaconitine and Bikhaconitine.

The action of these is, towards frogs, identical. Their toxicity appears to be practically equal and their effect generally similar to that of aconine (from aconitine). Their action is in the main curari-like in character.

"On the Physiological Activity of Substances Indirectly Related to Adrenalin." By H. D. **Dakin.** Communicated by Prof. E. H. Starling, F.R.S.

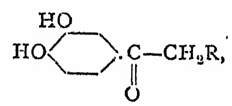
The following deductions are made provisionally, until further experimental evidence is available:—

(1) It appears that the catechol nucleus is essential for the production of physiologically active substances of the type of adrenalin.

(2) It is of importance that the hydrogen atoms of both hydroxyl groups in the catechol nucleus be unsubstituted.

(3) An alkyl group of low molecular weight (*e.g.* methyl, ethyl) attached to the nitrogen tends to produce a much more active substance than when an aromatic group is attached, whilst derivatives of piperidine, heptylamine, and benzylamine occupy an intermediate position.

(4) The reduction of ketonic bases of the type



where R is a simple aliphatic group, results in the production of bases with enormously increased physiological activity.

(5) In the substances examined there appears to be a connection between chemical instability and physiological activity, and *vice versâ*.

July 8.—"An Experimental Inquiry into the Nature of the Substance in Serum which influences Phagocytosis." By Dr. George **Dean.** Communicated by Prof. J. Rose Bradford, F.R.S.

The author's conclusions are as follows:—

(1) As has been shown by a number of workers, *e.g.* Denys, Metchnikoff, Savtschenko, Levaditi and others, there is produced in the blood serum of animals actively immunised by bacterial injections a specific immune substance which has among its properties that of preparing the microbe for phagocytosis.

(2) This immune substance is thermostable, resisting a temperature of 60° C. for several hours.

(3) In normal serum there is present a substance having a similar action and which also resists a temperature of 60° C. for hours, and may persist in the serum of the horse for years.

(4) The experiments recorded in this paper tend to confirm the idea that the substances are identical, *i.e.* that in normal serum there is present a small amount of the immune substance having the property of preparing the microbes for phagocytosis.

(5) Cocci fully occupied by the substance from heated immune serum when passed through fresh normal serum do not remove the substance from normal serum, whereas fresh cocci remove a large part of it.

(6) The converse of the above is also true, viz. that cocci fully occupied by the substance from normal serum do not remove the substance from immune serum, whereas fresh cocci do.

(7) The thermostable substance in normal serum is no doubt identical with the "fixateur" or "substance sensibilisatrice" of the French school and with Wright and Douglas's "opsonin."

Seeing that the terms "fixateur" and "substance sensibilisatrice" which have been employed by Metchnikoff's school to include the property of preparing the microbes for phagocytosis are used to designate a number of other properties of immune serum, it may be convenient to adopt Wright and Douglas's term of "opsonin" for the particular property in question. The only danger attached to such a course is that one might be led to regard the "opsonin" as actually a different substance, and not merely a property of immune serum.

PARIS.

Academy of Sciences, September 18.—M. Troost in the chair.—Preliminary note on the total eclipse of the sun of August 30 at Burgos: H. **Deslandres.** Details are given of the instruments set up and the observations attempted. Owing to clouds, the second and third contacts could not be observed. The corona was seen for a minute about the middle of totality. M. Fabry succeeded in making a photometric measurement of the total light of the corona, and an observation of the brightness of one of its points. M. Bernard also was successful in some photometric observations, and M. d'Azambuja in measurements of the heat spectrum of the corona. Details of the work will be published later.—Observation of the eclipse of August 30: H. **Andoyer.** The apparatus was installed at El-Arrouch, 32 kilometres from Philippeville, and the weather was very favourable. The object was to obtain as many direct photographs as possible. Forty-four were obtained, eleven during totality.—Observation of the solar eclipse of August 30 at Athens: D. **Eginitis.** The observations were made under good atmospheric conditions.—On the isolation of terbium: G. **Urbain.** In a preceding communication the author has described the separation of a rare earth characterised by a single absorption band $\lambda=488$, corresponding to an element named $Z\delta$ by M. Lecocq de Boisbaudran. This has been submitted to a long series of further fractionations, first as a double nitrate with nickel, and afterwards by precipitation with ammonia. The final product was 7 grams of an earth apparently homogeneous, for which the author proposes to reserve the name of terbium. The principal bands in the absorption spectrum are given, and the atomic weight, 159.2 (O=16).

NEW SOUTH WALES.

Linnean Society, July 26.—Mr. T. Steel, president, in the chair.—On dimorphism in the female of *Ischnura heterosticta*, Burm. (Neuroptera: Odonata): R. J. **Tillyard.** In February last, at Cook's River, about a dozen beautifully coloured examples of the pretty little dragon-fly, *Ischnura heterosticta*, Burm., which appeared to be males, were captured, together with half-a-dozen females of the ordinary dull blackish type. On examination it was found that, with the exception of three, all the supposed males were in reality a second form of female (form B) closely resembling the male. It is intermediate in shape between the male and the typical female (form A), the abdomen being thicker than in the male, but with the tip distinctly enlarged; while in colouring it almost exactly resembles the male, but bears not the slightest resemblance to the typical female. Both forms, however, possess the pale pterostigma on the forewing, whereas in the male this is black.—Notes on the older Tertiary foraminiferal rocks on the west coast of Santo, New Hebrides: F. **Chapman.** The examination of the oldest sedimentary rocks seen and collected by Mr. Mawson in the Island of Santo proves them to be of Miocene age (Aquitanian and Burdigalian). A point of particular interest brought out by the present investigations is the association of Lepidocyclina with the excentric forms of Miogypsina in the New Hebrides. From this it appears that faunas, distinct in the European area, were living together in the New Hebrides Miocene sea. A similar association of species occurs here as in the Miocene limestones of Christmas Island, and also of Madoura, and other parts of the Dutch East Indies, with which the New Hebrides marine area was most probably connected when these fossiliferous beach and shallow-water deposits were laid down.—On the occurrence of a bed of fossiliferous tuff and lavas between the Silurian and Middle Devonian at Cavan, Yass, N.S.W., similar in age and character to the Snowy River porphyries of Victoria: A. J. **Shearsby.**—The *rôle* of agglutination in immunity: R. Greig **Smith.** The research has shown that (1) normal typhoid bacteria are incapable of being absorbed by the leucocytes when these have been freed from adhering serum; (2) typhoid bacteria, when treated with active agglutinating serum which has been heated to destroy the opsonins, are agglutinated and are then englobed by the leucocytes; (3) typhoid bacteria which have been grown in agglutinating serum, heated or not heated, are also absorbed; (4) while active agglutinating serum prepares the microbes for inception by the phagocytes, the so-called chemical agglutinating substances do not possess this property; and (5) the *rôle* of agglutinin is, therefore, to coat the bacteria with a precipitate which is positively chemotactic towards the leucocytes; and thus, by facilitating the absorption of the microbes, agglutination plays an active part in immunity.

MODERN GEOLOGISTS AND THE "OLD MASTERS."

Ice or Water. Another Appeal to Induction from the Scholastic Methods of Modern Geology. By Sir Henry H. Howorth, K.C.I.E., D.C.L., F.R.S., V.P.S.A., F.G.S. Vol. i. Pp. xlvi+536. Vol. ii. Pp. viii+498. (London: Longmans and Co., 1905.) Price 32*s.* net.

THE two volumes before us must be regarded as parts of a complete work in which the author has set himself the task of disproving the usually accepted glacial theory. As he himself says in his preface, "the two volumes now published contain a large part of, though not all, my supplementary arguments against the glacial theory; a portion being still reserved for a succeeding volume which will also contain an enlarged presentation and justification of the theory I substituted for it in my 'Glacial Nightmare,' namely, the diluvial theory."

In the volumes under review the subject-matter may be considered under three heads:—(1) the theories which have been proposed to account for Glacial periods; (2) the efficiency of water as an agent of erosion; (3) the capacity of ice to produce the effects which have been assigned to it by modern geologists.

(1) *Theories of an Ice Age.*—The four opening chapters of the first volume are devoted to a criticism of the various theories, astronomical and geographical, which have been put forward in attempts to solve the problem of the Great Ice Age and of former periods of glaciation. Sir Henry is ever skilful in detecting the weak points in his opponents' armour, and here, as in his book on the "Glacial Nightmare," he has an imposing array of objections raised by others and himself to the various explanations which have been offered.

Our present inability to offer any adequate explanation of the Glacial period seems to be largely recognised; as Prof. Chamberlin has said, "The riddle remains to be read." This grieves the author greatly, perhaps unduly.

"It is not encouraging," he says, "to read of a succession of failures by men of parts and ingenuity in futile efforts to solve what is apparently an insoluble problem; to measure the waste of thought and time and oil involved in these efforts of the geological Sisyphus to roll the glacial snowball on to some stable foothold, and to see it roll down the hill in every case into the abyss where so many scientific hopes and efforts lie buried."

But is the waste so complete as the author seems to imply? Though the riddle is not yet read, the number of facts which have been garnered during the process of testing the inadequate explanations remain for use when seeking the correct solution, and many a minor point has already been settled.

The occurrence of Glacial periods is not the only climatic problem to which the geologist is without clue. We have not yet explained the existence of beds containing rich floras in Greenland. To the ordinary geologist the evidence for a Glacial period is as strong as that for the former occurrence of warmer conditions in Greenland, and he is hardly likely to reject the evidence in the former case any more than in the latter, simply because he has not yet arrived at an adequate explanation of the phenomena.

(2) *The Efficiency of Water as an Agent of Erosion.*—The author devotes several chapters to a discussion of the potency of the various agents of subaërial and marine erosion under existing conditions, and refuses to recognise the efficiency of these agents to do the work claimed for them by the great number of living geologists. He supports his arguments by a large number of quotations from various writers, ancient and modern, great and small. But we look in vain for any recognition of the principles of erosion which were laid down by G. K. Gilbert in his "Geology of the Henry Mountains," and form the basis of modern writings on erosion. He quotes Mr. Harker's paper on the subaërial denudation of Skye (*Geol. Mag.*, 1899, p. 485) to show that in that district "the agents of atmospheric degradation, erosion and transportation, are at the present time almost wholly inoperative," but ignores that writer's statement concerning the great erosion of the district in Tertiary times. Sir Henry, in fact, does not seem to have recognised the importance of the "base-line of erosion" as one of the controlling factors in the sculpture of a district, and this vitiates many of the arguments advanced in this section of the book.

But there is much in this section that is suggestive, especially the portions dealing with the effects of earth-movement and fracture in the production of valleys. In the "heroic age" of geology too much influence was undoubtedly assigned to these effects in accounting for valley-formation, and one cannot but feel that with the swing of the pendulum, and owing to the importance which geologists now attach, and rightly attach, to agents of erosion, the influence of movement accompanied by fracture, at any rate as an indirect factor, has been unduly minimised.

(3) *The Capacity of Ice to Produce the Effects Assigned to it.*—In the two concluding chapters of vol. i. and in the greater part of vol. ii., Sir Henry is directly at issue with the modern geologists, for in the majority of the phenomena which have been appealed to in support of the operations of ice he refuses to see any signs of ice-work. Notwithstanding the ingenuity with which he argues, we cannot see that he makes out a case. The Glacial period has been established as the result of cumulative evidence, and although there are many differences of opinion on minor points, geologists are agreed as to the occurrence of such a period in late Tertiary times in consequence of what most of them consider to be overwhelming evidence.

Here we must insert a word concerning the author's "old masters." In vol. i., p. 213, he takes his stand "with the old masters, Hopkins and Whewell, Conybeare, Sedgwick and Murchison. These men knew something more than geology; they were mathematicians and physicists as well." Again, on p. 460 he says:—"I do not hesitate myself to confess, and to be proud of the confession, that I

believe in the old men rather than in the new." It is true that in these cases he is referring to special points, but again and again one cannot but feel in reading the book that the writer pays undue regard for authority, without considering that his "old masters" were not acquainted with all the facts which we now possess, and that they themselves changed their views. Sedgwick, for instance, came to believe in an Ice age. Moreover, if these were old masters, so were Hutton and Playfair, Lyell and Buckland, whose views are not always so palatable to the author. It may be remarked, also, that a knowledge of mathematics and physics was not confined to the geologists of those days. One of the most ardent of the existing advocates of ice-erosion, concerning whose paper on ice action in Skye (*Trans. Roy. Soc. Edin.*, vol. xl., 1901) Sir Henry is silent in these two volumes, was a high wrangler, and took a first class in physics at Cambridge.

The theory of an Ice age was largely put forward owing to the existence of rounded and striated rock-surfaces and scratched and polished boulders. These resemble similar productions of modern ice to such a degree that the geologist has no more hesitation in referring them to ice-action than he has to assign the formation of the pebbles of a river to stream-action. The inference drawn from the existence of these phenomena has been supported by a host of other observations, biological as well as physical, and if Sir Henry should succeed in disproving the existence of an Ice age he will also break down the essential principle of geology, "that like effects imply like causes."

It would be impossible in a brief article to discuss all the questions raised in this part of the work. We must content ourselves with a few observations. Though reference is made now and again to the Greenland ice and to the ice masses of Spitsbergen, it is the glaciers of the alpine type to which most frequent appeal is made. To this we shall recur, but in the meanwhile would invite the author's attention to yet another treatise concerning which he is silent, where another type of ice work is described, namely, I. C. Russell's volume on the Malaspina Glacier (thirteenth annual report of the U.S. Geological Survey).

When describing the Till or Boulder-clay, the author quotes a description of it by Prof. James Geikie, and goes on to observe, "this being without question the most typical of so-called glacial deposit, it is a remarkable fact that no such deposit is now being made, so far as we know, by land-ice anywhere." He must have overlooked a passage in a paper to which he elsewhere refers, by Messrs. Garwood and Gregory, on the glacial geology of Spitsbergen (*Quart. Journ. Geol. Soc.*, vol. liv.). They say:—

"On the broad plain at the foot of Booming Glacier we found some square miles of a tough mud containing boulders and pebbles; it only needed to be dried and hardened to form an ideal Boulder Clay. Clearly this deposit had been laid down by land-ice."

The author objects to the sharp line which is drawn by many geologists to show the margin of the ice at its period of maximum extension, and denies the existence of any evidence for this, arguing that the Boulder-clay, the masses of gravel and loam, and the loess are genetically connected. Of this we shall doubtless hear more when the third volume appears.

Much is naturally made of the conflict of opinion among geologists concerning the occurrence of inter-Glacial periods, and the relative importance of land-ice and floating-ice in producing the phenomena generally taken to indicate the occurrence of a Glacial period. These questions are certainly not settled to everyone's satisfaction, but they in no way invalidate the conclusions which have been drawn as to the existence of an Ice age.

Though we do not agree with the author in his main conclusions put forward in this section of the work, we must admit that much that he writes is worthy of consideration, even though his views seem exaggerated. For instance, he argues that much of the material forming the drifts was broken up prior to the so-called Ice age, and this we believe to be true, even though the breakage did not occur in the manner advocated elsewhere by the author; but if true, it invalidates the appeal to modern Alpine glaciers to prove the inadequacy of ice as an erosive agent. The loose materials ready to hand at the beginning of Glacial times would supply the ice with the tools for rasping and grinding. As that material became comminuted, unless new material was supplied in abundance, the ice would become less effective as an eroder. Also ice, like water, has a base line of erosion beneath which it cannot work. This line may have been reached in the case of Alpine glaciers, and the supply of material to the sole have been also largely diminished, in which case one can no more argue from what Alpine glaciers are now doing as to the effects of land ice in the Glacial period than one can explain the cañons of the Colorado by reference to a little stream which has established its base level.

Throughout the work much has been made of the conflicting views of geologists as to the details of ice action. Sir Henry is obviously greatly impressed with the fact that in the long and arduous attempt to unravel the Gordian knot the skein sometimes seems to have become hopelessly twisted; but he who carefully studies the process of disentanglement sees that, notwithstanding the many kinks, the tangle is becoming less. The author, impatient of the slow process, has elsewhere attempted to cut the knot, and will evidently give reasons for this act in the third volume. We fear that the attempt will not be regarded as successful, either by the "ultra-glacialists" or by geologists in general.

We cannot recommend the book to geological babes and sucklings, but it will well repay perusal by the advanced reader. He will forgive the "energetic adjectives and adverbs," which are hardly necessary to a calm and dispassionate discussion, on reading the author's frank apology in the preface. The store of facts collected in the book is of the utmost value

to the student of glacial geology, though we wish that references to the original memoirs had been in all cases added. There are, as we have tried to show, many valuable criticisms and suggestions contained in the work. Lastly, it will prove a useful intellectual exercise to weigh the author's arguments in the balance. For these reasons we believe that readers who have an extensive acquaintance with the facts and principles of geology will read the book with profit—and with pleasure. J. E. M.

PHYSICAL CHEMISTRY.

Theoretical Chemistry. By Prof. Walther Nernst. Revised in accordance with the fourth German edition. Pp. xxiv+771. (London: Macmillan and Co., Ltd., 1905.) 15s. net.

THE fact that three further editions of the German text of Nernst's well known treatise on theoretical chemistry have been called for since the appearance of the original in 1893, affords ample testimony to its intrinsic merits. An English translation of the first edition by Prof. C. S. Palmer appeared in 1895, and this, until now, has been the only English version.

During the last ten years much valuable work has been carried out in the province of physical chemistry, and the publishers have recognised the necessity of bringing the English edition up to date. With that object Dr. R. A. Lehfeldt has translated the whole of the new matter contained in the fourth German edition and has revised certain parts of the original translation.

It has been the reviewer's experience to hear the original translation adversely commented upon, and it is perhaps to be regretted that the bulk of the old text remains as it was in the first edition. After careful perusal of the work, it is indeed difficult to suppress the feeling that a better result would have been attained by an entirely new translation of the fourth German edition.

Two new chapters in the work under review deal with "The Atomistic Theory of Electricity" and "The Metallic State." In the first of these an account is given of the electron theory and of the phenomena of ionisation and electric conduction in gases. In the second the nature of the metallic condition is discussed on the basis of results which have been obtained by the study of the freezing point curves and of the electrical conductivity of mixtures of metals. These chapters form very interesting reading, although, of course, it has not been possible within the compass of seventeen pages to give more than the briefest outline.

The space given to electro-chemistry has been extended from 26 to 46 pages, and the exposition of the subject-matter greatly improved. The application of thermodynamics and of the osmotic theory to electrochemical systems is now treated in separate chapters, and many new observations bearing on the theory of electrolysis have been incorporated.

It is not possible to mention more than a few of the alterations and additions which have been made in the text generally. One notes with pleasure that the somewhat abstruse exposition of energy relationships in the introductory chapter has been made more lucid. The discovery of the inert gases of the argon series has led to much discussion of late years in reference to the periodic classification of the elements, and these recent views are summarised in the chapter on the atomic theory.

Other important new sections deal with Werner's theory of molecular compounds, catalysis, the mechanism of autoxidation processes, tautomerism, and the kinetics of heterogeneous systems. The view that tautomerism is due to the co-existence in dynamic equilibrium of mutually transformable isomeric substances seems to be very probable in the light of recent work. In this connection the interesting observations of Hantzsch on the transformation of the tautomeric forms of nitrophenylmethane and similar bodies are recorded, but one looks in vain for any reference to Lowry's investigations on dynamic isomerism. In reference to the kinetics of heterogeneous systems and the mechanism of chemical change, it is now recognised that many gaseous reactions, usually regarded as taking place in a single phase, are possibly examples of changes essentially conditioned by phenomena at a boundary surface. The rate at which arsine or phosphine decomposes is in accord with the formula for a unimolecular change, but this agreement really affords no conclusive argument with reference to the mechanism of the change. The measured rate of change has possibly nothing whatever to do with the chemical change involved, but merely with a physical change at the surface of the containing vessel. In a third edition reference should be made to this in the section dealing with the mechanism of reactions on pp. 562–564.

Of necessity, much new work has had to be left unmentioned in the new edition, but the author is to be congratulated on the large amount of new matter which he has been able to introduce without appreciable alteration in the size of the volume. With the issue of this second edition one may confidently anticipate that Nernst's book will still maintain its position as one of the classics of theoretical chemistry.

H. M. D.

STOKES'S MATHEMATICAL AND PHYSICAL PAPERS.

Mathematical and Physical Papers by the late Sir George Gabriel Stokes, Bart. Vol. v. Pp. xxv+370. (Cambridge: The University Press, 1905.) Price 15s.

THE speedy completion of the reprint of Stokes's papers is matter of congratulation to the distinguished editor, to the Cambridge Press, and to all students of mathematical physics. The general character of the contents of this concluding instalment is sufficiently described in the following extract from Prof. Larmor's preface:—

"It will be observed that the present volume represents the period in which Sir George Stokes' scientific activities were mainly expended in the work of the Royal Society and of public Scientific Committees,

and in giving assistance to the investigations of others. The volume thus consists largely of additions and notes originally appended to memoirs by other authors."

Hence, although we meet abundant evidence of Stokes's constant occupation with scientific subjects, and of the characteristic generosity with which he placed his powers at the service of others, we miss something of the more spontaneous activity which characterised his earlier period. We find various proofs, however, that the subjects which had first fascinated him were never long absent from his thoughts; and occasionally they receive a flash of unexpected illumination. We may cite the various notes on water-waves, the brilliant little paper on semi-convergent series, and the admirable interpretation of Prof. Hele-Shaw's experiments on the flow of a viscous liquid between parallel plates. We have also a record of the keen interest which in the last few years of his life he took in the subject of Röntgen rays. The lecture (p. 256) which he gave to the Manchester Literary and Philosophical Society in 1896 was written out (with the help of reporters' notes) *after* delivery; bright and genial as it is, it gives no adequate idea of the buoyant freshness and vivacity which characterised the oral exposition.

The volume includes, by a happy determination, a collection of the papers set by Stokes in the mathematical tripos, and in the old Smith's Prize examination. It is well known that through this unusual channel several important scientific results were first made known to the world; for example, the notion of group-velocity, and the famous "Stokes's Theorem," respecting which we have an interesting historical note by Prof. Larmor. We suspect that a mathematical antiquarian might make further interesting "finds." If we are not mistaken, we detect prior publications of a remarkable theorem relating to the infinite product for sin x, and of a definite integral property of Bessel's functions, which are usually attributed to Weierstrass and to H. Weber respectively. Of course, no one, least of all Stokes himself, would attach much importance to the question of priority under these conditions; but such instances are of interest as showing, in unexpected directions, the singular vigour and independence of Stokes's mind.

The Royal Society obituary notice, with its authoritative appreciation of Stokes's scientific researches by one of his keenest admirers and disciples, forms a fitting accompaniment to this monumental publication. The volume is further adorned by an excellent photograph by Mrs. Myers, of date 1892.

The scientific world will await with great interest the publication of the "volume of biographical character, to be occupied in part by a selection from Sir George Stokes's voluminous scientific correspondence, including some unpublished manuscript material," which is promised in the preface. The great energy with which Prof. Larmor has discharged his present honourable task justifies the hope that we shall not have to wait too long for the proposed supplement.

OUR BOOK SHELF.

Notes on the Drawings for Sowerby's "English Botany." By F. N. A. Garry. Reprinted from the *Journal of Botany*, 1904–5. Pp. 276. (London: West, Newman and Co., 1905.) Price 6*s*.

The series of volumes known as "English Botany" was begun in 1790 by James Sowerby, the botanic artist, who engaged Dr. James Edward Smith, the possessor of the Linnean collections and founder of the Linnean Society, to describe the plants depicted by him. At first the name of the draughtsman only appeared on the title-page, but in 1795 a preface to the fourth volume by Smith acknowledged his authorship, and he was much annoyed in after years by "the flippancy with which everybody quotes "Sowerby," whom they know merely as the delineator of these plates, without adverting to the information of the work, or the name of the author." The artist and those who followed him preserved the original drawings of the phanerogams and vascular cryptogams, which ultimately came into the possession of the trustees of the British Museum, and are now in the department of botany. Here are to be found the drawings, with impressions from the original plates, and also from the third recast edition, laid down side by side on the same sheets. The drawings (which had been submitted to Smith for his criticism and his text which accompanied them) bear many notes and directions to the engraver, which are of great interest as showing not only the state of botany at the time, but mentioning the numerous contributors of plants to the work and its supplement. Mr. Garry has done excellent service in the laborious task of transcribing and editing these notes, which can now be read by those who have not seen the originals themselves. Turning over these pages, the writer is reminded of the days when, more than thirty years ago, he first made acquaintance with the drawings in the old rooms of the department at Bloomsbury, recalling the charm they possess for all who care for the history of the native plants of Great Britain.

Without going into detail it would be impossible to set out many most interesting items which are to be found in the pages of this modest reprint from the two years' supplements to the journal in which they made their first appearance. We have here glimpses of a big book in the making, which extended in the first instance to thirty-six volumes and closed in 1814 with a general index. Further discoveries and greater discrimination of critical forms induced the beginning of a supplement in 1831, which died out in 1866 in its fifth volume; the text in these later volumes was by many hands, amongst them the most active and critical of the botanists of the day. These last plates are now in the Fielding herbarium at Oxford, whence they were borrowed by the author so as to complete his work.

B. D. J.

A Text-book of Chemical Arithmetic. By Horace L. Wells. Pp. vii+166. (New York: John Wiley and Sons; London: Chapman and Hall, Ltd., 1905.) Price 5*s*. 6*d*. net.

In the preface it is stated that this book "is designed especially for the use of students of quantitative analysis, many of whom, even after having taken extensive courses in higher mathematics, show little ability to solve simple chemical problems. Certain portions of the work are suitable also for the use of those who are studying elementary chemistry." It appears, therefore, that an American professor is no better off than his English cousin in this matter of student arithmetic The difficulty is two-fold. In

the first place, the student has never been taught arithmetic in relation to actual measurements, but has been exercised in fictitious transactions with oranges and nuts, rods, poles or perches, and vats into which liquor flows at the rate of so many gallons a minute and out of which it flows (notwithstanding the dwindling pressure) at another exact and steady rate. The result is that the student has no idea of the relation of magnitude to measurement, and no opinion whatever on the subject of significant figures; he cannot use logarithms or a slide-rule, and is unpractised in contracted methods of computation. In the second place, it is very likely that he has no sound idea of proportion. Given a student in this condition —and it is still the common case—the teaching of what is called chemical arithmetic becomes a serious part of the duties of a teacher of chemistry. The fundamental numbers of chemistry—the atomic weights—are proportional numbers, and it may be said without exaggeration that the failure to realise this and the inability to see how proportional numbers may be used for the calculation of absolute weights, locate the real *pons asinorum* of elementary chemistry.

In these circumstances any well considered attempt to expound the elements of chemical arithmetic is to be welcomed, and Prof. Wells has certainly succeeded in writing something on the subject which is likely to be very useful. He does not quite descend to the meanest capacity, but he deals in a very clear way with the meaning of figures and the limits of accuracy in measurement and computation. He also gives a good survey of the chief types of chemical problems, including all kinds of analyses and the corrections of gas volumes. Great pains are taken to impress the student with the importance of using common sense and judgment whilst performing arithmetical operations, and to this end set rules and stereotyped formulæ are avoided. An appendix to the book contains tables, including a well printed set of five-figure logarithms. Altogether the work is one that may be warmly recommended to the notice of English teachers.

A. S.

The Physics and Chemistry of Mining. By T. H. Byrom. Pp. xii+160. (London: Crosby Lockwood and Son, 1905.) Price 3s. 6d. net.

THIS elementary class-book supplies information required for such examinations as the Board of Education principles of mining, stage i. The idea is a good one, as the principles of pure science upon which mining practice is based are apt to receive scant attention in mining classes. The author, who is chemist to an important colliery company, has, as lecturer at the Wigan Technical College, become acquainted with the needs of students, and he gives in concise form much useful information regarding the atmosphere, the laws relating to the behaviour of gases, the diffusion of gases, the composition of the atmosphere, water, carbon, fire-damp, combustion, coal dust, explosives, the composition of coals, the analysis of coal, the strata adjoining the Coal-measures, magnetism and electricity. The language is simple, and chemical symbols are sparingly used. There is, however, a want of uniformity in nomenclature that might confuse the beginner. The terms "carbonate of magnesium" (p. 96) and "magnesia carbonate" (p. 125), "iron oxide and aluminia" (p. 46) and "iron peroxide and alumina" (p. 125) are examples. The author, too, should not have included Cumberland hæmatite among the ironstones, nor granite among the strata adjoining the Coal-measures.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

On the Absorption Spectrum of Benzene in the Ultra-violet Region.

IN the *Transactions of the Chemical Society* for August Messrs. Baly and Collie, referring to the previous work of Baly and Desch (*Trans. Chem. Soc.*, 1904, lxxxv., 1029, and 1905, lxxxvii., 766) on the absorption spectrum of acetylacetone and its derivatives and the conclusions arrived at, namely, that the absorption band is caused by dynamic isomerism, or rather isodynamic changes, are led to infer from the occurrence of bands in the spectrum of benzene that these also are caused by the making and breaking of the carbon bonds in the molecule of the substance. I have given a similar, but not identical, explanation of the cause of the bands in the spectra of uric acid, murexide, and the ureides, and have pointed out that there is but little difficulty in accepting a like explanation in order to account for the bands in aromatic hydrocarbons, seeing that this would harmonise with Kekulé's view of the constitution of benzene. The particulars are contained in two papers communicated to the Chemical Society on May 17, but as they are still unpublished I cannot refer to them in detail.

Messrs. Baly and Collie consider all the possible phases in change of linking between the six carbon atoms in benzene, and assign a band to each phase. In doing this they feel justified in assuming that an even number of carbon atoms is concerned in each individual process, and in accordance with chemical evidence it could scarcely be imagined otherwise. They argue that there are only seven different makings and breakings of bonds possible, to which seven different absorption bands should belong, and on investigating the spectrum of benzene they find only seven bands. Seven bands were photographed (*Phil. Trans.*, 1879), as they remark, by Hartley and Huntington, but no measurements are given. The wave-lengths of lines in the ultra-violet had not been determined at that time (1878), with the exception of the principal lines of cadmium measured by Mascart, hence the reason for the absence of measurements.

In a subsequent observation (Hartley and Dobbie, "Notes on the Absorption Spectrum of Benzene," *Trans. Chem. Soc.*, 1898, lxxiii., 695) seven bands were photographed and measured, but one of these appeared to differ from the others in constitution, and it was indicated as doubtful; it is also a feeble band. The general character possessed by the first six bands was most distinctly marked in the four strongest; each was stronger and generally sharper towards the side where the rays of shorter wave-lengths lie, and was weakened in the opposite direction, as if the bands were composed of groups of lines occurring closer together and being stronger towards the more refrangible edge. Baly and Collie appear to have overlooked some points of importance in this communication, since they state that Hartley and Dobbie found only six bands, and that the measurements of the actual heads of the bands are not given. They give a series of numbers derived from Hartley and Dobbie's measurements which for comparison with their own are printed in a parallel column. The gist of the paper by Hartley and Dobbie was to show the structure of the benzene absorption spectrum partly by measurements and partly by the aid of a photograph. The bands which distinctly showed the structure were numbered, but unfortunately the manner in which the photograph was reproduced failed to render delicate details which were visible on the original plate. The statements contained in the paper appear, however, to have been clearly and fully understood by W. Friederichs, who photographed the vapour of benzene with a Rowland grating. He found fifty-six bands of absorption in its spectrum in the ultra-violet, which are arranged in eight groups, and he compared the principal lines of each group with the

points of maximum absorption, or most persistent edges in each of the bands measured by Hartley and Dobbie. This is shown in the following statement quoted from his paper (Wilhelm Friederichs, *Zeit. für wissenschaftliche Photographie*, B. iii., 154–164, 1905).

I have added in italics the wave-length numbers corresponding to Baly and Collie's oscillation frequencies for comparison:—

	Vapour. Friederichs. λ	Solution in alcohol. Hartley and Dobbie. λ	Difference.	Baly and Collie. λ
(1)	2670	2681	11	*2683*
(2)	2633	—	—	*2656*
(3)	2588	2599	11	*2610*
(4)	2526	2541	15	*2554*
(5)	2458	2485	27	*2484*
(6)	2404	2429	25	*2433*
(7)	2356	2376	20	*2380*
(8)	2305	2330	25	—

He points out that the bands of the substance in solution which without doubt correspond with those of the vapour are all shifted towards the red, as might be expected, but that the shift appears to be greater the smaller the wave-lengths of the absorbed rays. The comparison of Baly and Collie's numbers with those of Hartley and Dobbie is very interesting in this connection, inasmuch as they show a close general agreement in their divergence from the measurements of Friederichs. Furthermore, the following points may be noted:—

First, the omission of the second band in Hartley and Dobbie's spectrum; second, the omission of the eighth band by Baly and Collie; third, there is a close agreement between Hartley and Dobbie's and Baly and Collie's numbers in the first, fifth, sixth, and seventh bands, but the two sets of measurements for the third and fourth bands differ more widely than the others.

It may be mentioned that the second very narrow band is visible on the photographs taken by Hartley and Dobbie, though it can scarcely be considered as measurable; no doubt a longer exposure would have rendered it more plainly. Those who have measured similar series of bands in the visible region, for example, those in the spectrum of potassium permanganate, which are also eight in number, will appreciate the close approximation of the above figures.

W. N. HARTLEY.

Royal College of Science, Dublin, September 19.

Rhymes on the Value of π.

THE following rhyme is in imitation of the French and German verses given in NATURE (August 17) in which the number of letters in each word correspond to a numeral in the value of π. The three concluding lines are somewhat obscure; it seems to have occurred to the author that the method is a misuse of language, and he expresses the hope that NATURE will take a more lenient view than Dr. Johnson might be imagined to express.

To the Editor of NATURE.

Sir,—I send a rhyme excelling
3 1 4 1 5 9
In sacred truth and rigid spelling.
2 6 5 3 5 8
Numerical sprites elucidate
9 7 9
For me the lexicon's dull weight.
3 2 3 8 4 6
If "Nature" gain,
2 6 4
Not you complain,
3 3 8
Tho' Dr. Johnson fulminate.
3 2 7 9

F.R.S.

The Celtic Pony.

IN a review, signed "R. L.," of "The Faröes and Iceland," in NATURE of September 21 (p. 506), I was surprised to read that I had credited Prof. Ewart "with being the first to regard Przewalsky's horse as a variety of *Equus caballus*." I have just re-read the paragraph relating to the wild horse in my "Appendix on the Celtic Pony," and I can find no passage which, it seems to me, could by any possibility be made to bear this strange construction.

Sanson's subspecies *E. c. hibernicus* appears to include all the various ponies of the British Isles, the Breton in France, as well as the horses of Iceland, Norway, and Sweden. It has been recognised for some time past that the Icelandic horses are of two different types, while the Swedish horses are admittedly very mixed. Moreover, as a result of a recent tour in Norway, it has become evident to me that there are in that country at least two distinct kinds of native horses (represented by the pure fjord horse and the Gudbrandsdal horse). In view of these considerations, the statement that the Celtic pony is "probably inseparable" from the somewhat heterogeneous assemblage (as it now appears to be) included under *E. c. hibernicus* becomes a little obscure. But, as "R. L." points out, I did *not* make this statement. I grant, however, that it might have been better had I made some allusion to this matter.

But why I should have been expected in an "Appendix on the Celtic Pony" to have entered into a discussion as to the proper technical name to apply to *E. przewalskyi* or to have recorded an irrelevant criticism of Prof. Ridgeway's new name of *E. c. libycus*, I am at a loss to understand.

FRANCIS H. A. MARSHALL.

The University, Edinburgh, September 24.

GREEK ARCHÆOLOGY.[1]

THE archæologist justly ranks himself as a contributor to the world's knowledge on the same level as those who discover previously unknown forces in nature or new facts in the life-history of animals, extinct or living. Archæology, which is a branch of the great science of anthropology, discovers and correlates new facts in the early history of civilisation. Greek archæological discovery must always be of most especial interest, since it tells us of the origins of that early civilisation of the Mediterranean basin from which our present-day culture is derived. One of the most welcome yearly publications dealing with the subject is the "Annual of the British School at Athens," the tenth volume of which lies before us. It deals with the British work of 1903–4, besides containing independent articles on matters of archæological interest.

Dr. Arthur Evans's work at Knossos does not occupy so much space in the "Annual" as usual. The discoveries of the year, while most interesting, were not so new and epoch-making as those of former years, and the chief find, the tombs of "Ja'far's Papoúra" (τοῦ Τζαφὲρ ἡ Παπούρα) and Isópata, are described by Dr. Evans in a separate communication to *Archaeologia*. The first-named tombs, on a hill north of the Knossian palace, were of various types; (1) chamber-tombs approached by a *dromos*; "in many cases these contained clay coffins, in which the dead had been deposited in cists, their knees drawn towards the chin"; (2) shaft-graves; (3) pit-caves, "or pits giving access to a walled cavity in the side below." In 2 and 3 the skeletons were extended at full length. On the hill of Isópata, about two miles north of Ja'far's Papoúra, a very fine tomb, no doubt that of a king, was found, with a smaller one by its side. The larger consisted of a square chamber of limestone blocks, eight metres by six, "with the

[1] "The Annual of the British School at Athens," No. x. Session 1903–4. (London: Macmillan and Co., Ltd.)

side walls arching in 'Cyclopean' fashion towards a high gable," which had long ago been quarried away. The lofty entrance-hall was approached by an imposing rock-cut dromos. "In the floor of the main chamber was a pit-grave covered with slabs. Its contents had been sifted for metal objects in antiquity, but a gold hairpin, parts of two silver vases, and a large bronze mirror remained to attest the former wealth of such. A large number of other relics were found scattered about, including repeated clay impressions of what may have been a royal seal. Specially remarkable among the stone vessels is a porphyry bowl of Minoan workmanship, but recalling in material and execution those of the Early Egyptian Dynasties. Many imported Egyptian *alabastra* were also found, showing the survival of Middle Empire forms besides others of Early Eighteenth Dynasty type. Beads of lapis lazuli also occurred, and pendants of the same material, closely imitating Egyptian models. Four large painted jars with three handles illustrate the fine 'architectonic' style of the Later Palace of Knossos, in connexion with which the great sepulchral monument must itself be brought."

The form of this square-chambered mausoleum is unique, and may be compared as a contrast with the *tholos* or beehive tombs of the Greek mainland. Dr. Evans says that he was tempted to recognise in it the traditional tomb of Idomeneus, but that the other tomb near by, which is cut in the rock, is hardly considerable enough to be taken for that of Meriones, which tradition placed beside the other. Nevertheless, Dr. Evans's identification may be correct; the important tomb on the slope of the hill looking towards Knossos and Heráklcion would naturally be identified by the later Greeks as the resting-place of one of the greatest heroes of the island, and any other tomb close by, whether it were as large as the first or not, would then be dubbed the grave of his legendary companion.

Another interesting discovery was made outside the limits of the palace in the shape of a Minoan paved way leading due west from the "Stepped Theatral Area" discovered in 1903 towards the modern road to Candia. By the side of this were found magazines with interesting deposits of inscribed tablets apparently referring to the contents of the ancient royal stables and armouries; chariots, wheels, and yokes are pictured on them, and large numbers of arrows. Close by were found bundles of the very arrows mentioned on the tablets. A later Roman causeway overlay part of this road, but this was evidently merely a coincidence, for that the knowledge of the old road was lost after the close of the Minoan period is shown by the fact that during the early Hellenic ("Geometrical") age a well was sunk over the old Minoan way and driven right through it. This is a very interesting proof of the entire break in culture between the Mycenæan and "Geometrical" peoples in Crete, and is a strong argument in the armoury of those who believe that the Minoans or Mycenæans were not Greeks in our sense of the word at all, but a totally different race probably of non-Indo-European speech.

In the palace itself interesting finds were made. A section cut in the western court enabled more accurate notes of the stratification of the ancient remains to be made, resulting in a further subdivision of the Minoan period and a more accurate placing of the polychrome ("Kamáres") pottery as belonging to the stratum "Middle Minoan II." The Kamáres pottery is known by Egyptian evidence to be contemporary with the twelfth dynasty. The palace as it stands is late Minoan, which corresponds with the Egyptian evidence, which dates the Keftians who brought vases of the grand Knossian style to Egypt as contemporary with the eighteenth dynasty. Beneath the Minoan strata was found a deep Neolithic stratum going down to the virgin rock. From the modern surface of the ground to the base of "Early Minoan I." (the sub-Neolithic period) measures 5 m. 33 cm. in depth; the Neolithic stratum is 6 m. 43 cm. The date B.C. of the eighteenth dynasty and the late Minoan palace is roughly 1500; that of the twelfth dynasty and Middle Minoan II. about 2200. "Middle Minoan II." is 2 m. 50 cm. below the surface; the virgin rock is 7 m. 75 cm. From this the great age of human settlement at Knossos will be seen at a glance. A peculiarity of the Knossian site is that the late Minoan remains are found almost immediately beneath the modern surface of the ground. This points to the place having been kept clear of later buildings, the tradition of its sanctity and heroic associations having always persisted.

Fig. 1.—Two polychrome vessels of the Middle Minoan Period. From the Palace at Knossos.

An earlier western façade of the central court was also discovered, and further cists belonging to the first period of the later palace, in the magazines. The discovery of fragments of reliefs in these cists (one of them, representing the head of a charging bull, was identified by one of the workmen as a portrait of the devil) led Dr. Evans to suppose the existence of upper halls, to which the reliefs had belonged, above the magazines. These halls seem undoubtedly to have existed, and a ramp led up to them from the "Stepped Theatral Area."

These are all very interesting results, and show how much there is still to be discovered at Knossos.

The excavations of the British School at Athens at Palaíkastro are described by Messrs. Dawkins and Currelly. The remains of a shrine of the Cretan snake-goddess (analogous to those at Knossos and Gourniá) were found, besides some interesting *larnax*-burials. Mr. Dawkins gives a careful analysis of the pottery found in the town ruins, and a very useful comparative table of the strata of the Minoan period, with illustrative examples from Cretan and non-Cretan sites (p. 195). Mr. H. R. Hall publishes a

photograph of an important Egyptian tomb-painting depicting Minoan ambassadors bringing rare vases of Cretan workmanship to the court of Queen Hatasu or Hatshepsu at Thebes.

In connection with the point raised anent the Minoan way, already described, at Knossos, that there was a great gap in history between the last (presumably non-Aryan) Minoans and the first (Aryan) Hellenes, we may note that Mr. R. S. Conway returns to the charge in defence of the "Aryanism" of the Minoans in another article on the Eteocretan inscriptions of classical times, which he considers to represent the speech of the Minoan Cretans. There is no proof of this whatever, and even if Mr. Conway were to succeed in proving the Indo-European character of this late "Eteocretan" language up to the hilt, this would not in the least shake our conviction that the old Minoans spoke a non-Indo-European tongue. The craniological and archæological evidence must be taken into consideration as well as the philological, which can apparently be twisted into meaning anything that the investigator wishes. The craniologist assigns the Minoans to the "Mediterranean" race, to which the ancient Egyptians also belonged; and the archæologist brings the Minoan and Egyptian cultures back almost to a common origin. Further, Mr. Conway's idea goes counter to those of many of the philologists themselves, especially Kretschmer, whose view that the præ-Hellenic speech of Greece was non-Aryan agrees with the results of craniological and archæological research, and is generally accepted now.

This completes the list of articles dealing directly or indirectly with the Minoan or Mycenæan antiquities, the relics of the prehistoric culture of Greece.

Mr. Dawkins contributes an interesting philological article, entitled "Notes from Karpathos," describing the linguistic phenomena of that little known island, which he visited two years ago. The dialect seems to be more divergent from that of Crete than might have been expected. It presents all the peculiar dialectical phenomena of the Southern Ægean. Such pronunciations as "hyaloshorzho" (χγαλοšορžο) for Καλοχωρίον, which strike one so forcibly in Crete, are well represented. Aberrant grammatical forms are not uncommon. The old third plural in -σι(ν) survives. Here we have a considerable difference from Cretan practice, which prefers third plural in -νε: "they went," in Cretan ἐφύγανε, is in Karpathian ἐφύγασι(ν), and "they are walking," Cretan πατούνε, is in Karpathian πατοῦσι(ν), which sounds quite "Attic." This is an interesting survival. Articles of this kind are of great use and value.

Mr. M. N. Tod and Mr. E. S. Forster add contributions to epigraphic scholarship, and the latter also describes Laconian topography and archæological sites. Mr. A. J. B. Wace has an article on Greek grotesque figures as charms against the evil eye. The modern Hellenes wear charms in the shape of little silver or coral figures of hunchbacks (*gobbi* or *gobbetti*) for the same purpose.

Dr. Schäfer's German article on "Altägyptische Pflüge, Joche," is apparently published in the "Annual" on account of the ancient Egyptian basket figured on p. 140, which is of the same type as the Greek *liknon*, discussed by Miss Jane Harrison in her note on the "Mystica Vannus Iacchi," which follows. Otherwise one would have thought that its proper place would have been found in an Egyptological publication. The Berlin Museum has a large collection of ancient Egyptian agricultural implements, which are, however, of course all, with the exception of a fine plough and the basket aforesaid, of well known types equally well represented in other museums.

H. R. HALL.

SOUTH AFRICAN MEETING OF THE BRITISH ASSOCIATION.

LETTERS from local correspondents in South Africa have just brought us some notes upon the recent meeting of the British Association. During the progress of the meeting several cablegrams which appeared in the *Times* were summarised in these columns, so that many of the matters mentioned by our correspondents have already been recorded. Dr. J. D. F. Gilchrist has sent us an account of the part of the proceedings of the association at Cape Town, and the following particulars in so far as they are connected with Cape Town are from his communication. As, following our usual custom, we have arranged with officers of the sections for reports of the proceedings at sectional meetings, it is unnecessary now to give any account of these meetings.

Dr. Gilchrist states that as early as August 6 some of the British Association visitors began to arrive in Cape Town by the *Tintagel Castle*; eighteen more arrived on August 8 by the *Kildonan Castle*, and forty-three by the *Durham Castle* on August 12. The main body, however (eighty-six), including most of the official party, arrived by the *Saxon* on Tuesday, August 15.

The voyage of the main party was favoured by excellent conditions of weather, and the usual routine of life and entertainments on board was diversified by lectures by members on appropriate subjects of interest, and in one or two cases by scientific work, such as the collecting of plankton and temperature observations of sea and air. A few advance copies of "Science in South Africa," a handbook prepared on the occasion of the visit, were on board, and afforded some insight into the scientific work and problems engaging the attention of South Africans.

On arrival at Cape Town Docks the passengers were transferred to the train waiting alongside, and about 10 a.m. on August 15 arrived at the main station, where they were met by the mayor, the hospitality committee, and others. The council of the association met at 12 noon and the general meeting at 2 p.m., and the formal business was quickly got through.

The details of the somewhat extensive programme were in an advanced state of preparation, the general plan and coordination of the whole having been undertaken by a central organising committee for South Africa, the local details by the several reception committees at the seven local centres to be visited. These local committees were subdivided into entertainment, hospitality, excursions, and finance subcommittees.

Great assistance was rendered by Mr. Silva White, assistant secretary of the British Association, who arrived some weeks before the first meeting and took over the general direction of, and responsibility for, the arrangements. He arranged for the services of four assistant secretaries, who were instructed as to the details to be carried out on certain sections of the programme allotted to them, an arrangement which was fully justified by the subsequent results.

The formal business of the association commenced with the presidential address, which was delivered on the evening of August 15 in the City Hall, which had just been completed in time for the meeting. The work of the various sections began the following day, and occupied the mornings from Wednesday, August 16, to Friday, August 18, half the sectional work being transacted at Cape Town and half at Johannesburg.

In the afternoon of August 16 there was a large attendance at the Governor's garden party, and in the evening the Mayor met the visitors at a reception in the City Hall.

A large number of papers were read on the mornings of the two following days. As a special feature of the papers and presidential addresses was their bearing on South African questions, exceptional interest was taken in the sectional proceedings.

The following excursions were made on August 17:—(1) botanical excursion to the Kloof Nek; (2) visit to Groote Schuur for lady members of the British Association by invitation of the Loyal Women's Guild of South Africa; (3) visit to the Central Electric Station of the Cape Town Corporation. In the evening a lecture was given in the City Hall before a crowded audience on "W. J. Burchell's Discoveries in South Africa," by Prof. E. B. Poulton, F.R.S.

The afternoon of August 18 was devoted to excursions; and a reception was held by Sir David and Lady Gill at the Royal Observatory. In the evening a lecture was given in the City Hall on "Some Surface Actions of Fluids" by Mr. C. V. Boys, F.R.S.

Saturday, August 19, was devoted entirely to the following excursions:—(1) geological excursion; (2) Wellington; (3) De Beers Explosive Works; (4) Houts Bay; (5) Groot Constantia and Tokai; (6) Robben Island; (7) Stellenbosch; (8) Admiralty Works at Simons Town and Marine Station at St. James; (9) Table Mountain *viâ* Saddle Face; (10) Table Mountain *viâ* Wynberg; (11) Table Mountain *viâ* Kasteel Poort.

Dr. W. Flint (librarian to the Houses of Parliament), who accompanied the association throughout its entire journey, has undertaken to send NATURE some account of the Natal, Johannesburg, and Rhodesian proceedings. The following notes are from a letter just received, with the promise of a further instalment by the next mail.

On the termination of the meeting in Cape Town the main body of the members of the association proceeded to Durban in the Union Castle steamers *Saxon* and *Durham Castle*. The former steamer left the docks on Friday evening, August 18, and its passengers were debarred from taking part in the numerous Cape Town excursions which had been arranged for the Saturday. The *Saxon* passengers had, however, the advantage of brief visits to Port Elizabeth and East London, at each of which ports of call a few hours were spent, and hospitality was tendered by the mayor and citizens. The *Durham Castle* proceeded direct to Durban, and, making a record passage, arrived a little in advance of the mail steamer. A party of some thirty persons elected to proceed to Durban overland in one of the trains provided by the Cape Government, which was proceeding to Durban to meet the steamers. A special geological excursion through the Hex River Pass on to the Karroo captured a few enthusiasts, who, under the guidance of Mr. A. W. Rogers, of the Cape Geological Survey, spent a few days which proved to be of great interest. These members necessarily had to deprive themselves of the pleasure of the Natal section of the tour. The trip overland to Durban, which occupied four nights and three days, was unanimously voted a great success, and as several of the passengers are proceeding to England by Beira and the east coast, the opportunity of seeing the Karroo was much appreciated.

The two days spent in Durban and the neighbourhood were very fully occupied, the hospitable ideas of the mayor and his numerous helpers having provided a very attractive programme. Tuesday morning, August 22, was occupied in settling down and taking the bearings of the town, and early in the afternoon a public welcome was tendered by the mayor, Mr. Henwood, to which Prof. Darwin responded. A garden party generously given by Sir Benjamin Greenacre, for which very elaborate preparations had been made, was partly spoiled by a heavy thunderstorm, but large numbers braved the downpour and were rewarded by seeing a few of the glories of the Berea.

Two lectures were given in Durban to very large audiences. Mr. Douglas W. Freshfield discoursed on "Mountains—the Highest Himalaya," and Prof. W. A. Herdman on "Marine Biology."

The second day in Durban was occupied chiefly with excursions. Perhaps the first place was taken by the entertainment provided by the Hon. Marshall Campbell at the Mount Edgecombe Sugar Estate. The contrast afforded by a Zulu war dance and a demonstration by Christian native girls was an object lesson which many were glad to have seen.

The excursion to Umkomaas was scarcely less enjoyed, the romantic subtropical scenery being a revelation to many of those who were privileged to be present. The botanists especially seemed to revel in the opportunity, the wealth of Strelitzias in their native habitat being particularly attractive.

On Thursday morning, August 24, the whole party left in four trains, to be known henceforth as A, B, C, and D trains, and arrived about mid-day in Maritzburg. The journey is one of the most attractive in South Africa, passing in its earlier stages through sugar, banana, and pine-apple plantations, and ascending rapidly to the Botha Hill heights, from which views of singular extensiveness and beauty are obtained. On reaching Maritzburg admirably complete arrangements were found to have been made, and members found themselves welcomed with great cordiality by Mr. A. W. Kershaw, the Mayor, and a host of willing citizens who had thrown themselves with great zeal into their task.

His Excellency Colonel Sir H. E. McCallum held a garden party at Government House which was a very successful function, and in the evening the Town Hall was thronged when His Excellency and the Mayor gave addresses of welcome. Colonel Bruce followed with a lecture on "Sleeping Sickness" which created great interest.

On the following day there were visits to the Government experimental farm and the Government laboratory, but it is to be feared that these were somewhat overshadowed by the Kafir dance and wedding which took place at Henley. The wedding was that of a young hereditary chief, and was preceded by the various dances and ceremonies customary on such an occasion. Never, probably, were so many photographs taken on a single day in Natal. The cameras were legion, and some of the photographers were not content with less than two or three dozen of pictures.

In the evening the young Natalian member of the official party, Mr. H. D. Ferrar, by special request, gave a lecture on "Antarctic Regions," he having been a member of the *Discovery* Antarctic Expedition.

Both in Durban and Maritzburg all members of the association had free use of the municipal trams, and nothing was left undone to ensure the comfort and enjoyment of the visitors, who in their turn were loud in their praises of the reception accorded.

TWO REPORTS OF THE FRENCH GLACIER COMMISSION.

A RECORD of observations on snowfall and avalanches undertaken by the Forestry Department of Savoy during 1904 on the south-west flank of Mont Blanc is contained in a paper entitled "Observations sur l'Enneigement et sur les Chutes d'Avalanches," issued by the Commission française des Glaciers (Paris: Club Alpin français). The

paper is a continuation by M. Mougin of his report of June, 1903, and deals with the results obtained from the seven instruments placed at appointed stations between the village of Houches and the Aiguille du Goûter. Unfortunately, the snow-gauge placed on the Aiguille du Goûter was destroyed by a party of young students from Geneva who attempted the ascent of Mont Blanc without guides in 1902. On the Tête-Rousse, again, the instrument was found completely empty; fortunately, however, the platform snow-recorder, placed on the glacier, enabled an estimate of the snowfall to be made.

The general results derived from the records of these seven stations show that between 1000 metres and 3200 metres the snowfall increases with altitude, but the results are not altogether satisfactory. Thus the record at 2100 metres gives a fall equivalent to 0.3194 mm. of water only, whereas the stations above and below show falls of 1.848 mm. and 0.491 mm. respectively.

Even if the upper station is excessive, the station above at 2850 metres at the Pierre-Rondestill shows an increase, being 0.4461 mm.; it is possible, therefore, that the mouth of the instrument has become blocked by a film of verglas. With regard to the large fall recorded at 2550 metres, it is possible that here we have the altitude at which the greatest precipitation takes place. The loss of the instrument at the summit of the Aiguille du Goûter is all the more to be regretted on this account, as it would undoubtedly have thrown light on this point, and it is to be hoped that the instrument may speedily be replaced.

The report gives a detailed description of the instruments used. These consisted of horizontal boards placed one metre above the ground, and also of Vallot's snow-gauges of a modified design.

Comparative experiments were made during the winter at Chambéry between the official rain-gauge, the Vallot tubes, and the snow-table. The results are expressed in tables and by curves. No useful comparisons could be made between the rain-gauge and the Vallot tubes, but the results obtained with the latter instrument are compared with those obtained with the snow-table, and are expressed both in depth of snow and amount of water melted. The small number of snowstorms during the winter of 1902–3 was also unfavourable to any definite conclusion being arrived at; further experiments are required.

The report ends with tables showing the snowfall and number of avalanches which fell in Savoy during 1902, also the damage done to forests, roads, and water-courses, and accidents to men and animals.

Another report received from the Commission française des Glaciers deals with the observations by M. Paul Girardin on the glaciers of Maurienne, Vanoise, and Tarentaise during August and September, 1903, and also with the glaciers of the massif of La Vanois in 1903, by J. A. Favre (Extrait de l'Annuaire du Club Alpin français, vol. xxx., 1903). M. Girardin arrives at the conclusion that these glaciers are retreating, the amount varying in different glaciers and even in different lobes of the same glacier. The general law is, therefore, complicated by local shade, &c. Retreat is most marked where surface moraines are absent, while those covered thickly with débris are more stationary. The rate of retreat has, however, diminished during the last ten years.

In the massif of the Vanoise we find the same story. Glaciers like the Grands-Couloirs, Pelvoz, &c., are all losing in thickness. In the case of the Pelvoz a new medial moraine has appeared owing to the marked ablation, while a glacier marked on the map north of the Col d'Aussois has completely disappeared.

E. J. G.

INTERNATIONAL METEOROLOGICAL CONFERENCE AT INNSBRUCK.

Second and Third Meetings.[1]

AMONG the various points brought under notice, the president, Dr. Pernter, stated that M. Violle wished that his proposals made to the meeting at Southport on the question of solar radiation should be discussed. After considerable deliberation, it was resolved that the principal observatories should be requested to make observations of solar and terrestrial radiation. Measurements should be made daily, those of solar radiation at 11h. a.m. or from 11h. a.m. to 1h. p.m., and those of terrestrial radiation at 10h. p.m. or from 10h. p.m. to 12h. p.m. The apparatus used should be exclusively Angström's compensation actinometer.

Upon the subject of excessive rainfall, Dr. Landa, of the k.k. hydrographisches Central-Bureau (Vienna), proposed (1) that meteorological offices should be invited to inquire into the causes of origin of cases of excessively heavy rainfall over large areas, including those which have already occurred, and any that may occur in future, in the districts under their supervision, and to publish the results of their investigations, and (2) that it should be recognised as useful to investigate the historical documents of various countries for particulars of abnormal meteorological occurrences, such as floods, droughts, very severe winters, &c., and to classify and publish the results of their researches.

The classification of meteorological stations, according to the nature of the work carried out, was referred to the International Meteorological Committee, as was also the definition of such phenomena as hoar-frost, silver-thaw, glazed frost, &c.

On the important question of long series of homogeneous observations, necessary for the study of secular variations, the conference adopted Dr. Hellmann's proposal that central meteorological offices should establish in their respective organisations one or more secular stations, according to the extent of the country, and should carry on the observations as uniformly and continuously as possible. At the same time, the conference expressed the hope that old series of observations might be critically discussed and published.

On the proposal of M. Rosenthal, the conference requested General Rykatcheff to undertake, on the part of the Central Physical Observatory, St. Petersburg, the publication of a summary of the results of observations made during the last century. Dr. Hellmann was requested to assist in the preparation of this useful work.

Prof. von Bezold raised the question of the status of the conferences of directors, and of the International Meteorological Committee; he thought they should maintain an official character, so far as possible, and that the number of meetings should be as few as practicable. After considerable discussion, a proposal by Dr. Hellmann was adopted, viz. that the conference should request the International Meteorological Committee to draw up a standing order relating to the International Meteorological Organisation, at the same time taking note of the historical development of the committee. This rule, dealing with conferences of directors, the international committee, and the subcommittees, should be submitted to the next conference of directors for discussion.

M. Froc made a communication respecting the organisation of the meteorological service of the

[1] An account of the opening meeting appeared in NATURE of Septem 21 (p. 510).

Chinese Maritime Customs. We have not yet received the protocol of the last meeting, but we may state that it included reports of the various commissions.

With regard to the Solar Commission appointed in 1903, complete arrangements were made for bringing together all data necessary for the study of simultaneous solar and terrestrial changes. Letters had been received from Prof. Hale and M. Deslandres placing their photospectroscopic results at the disposal of the commission.

INTERNATIONAL UNION FOR COOPERATION IN SOLAR RESEARCH.

AT last the importance of solar research is asserting itself, even in the minds of some who in the past have shown it scant favour. It is not a little remarkable that during last month two international bodies held meetings, both of them concerned with solar observations, the one, the Solar Commission, established in 1903, which met at Innsbruck, dealing with them in relation to the meteorological changes on the earth, the other, the Solar Union, established in 1904, which met at Oxford, dealing with the physics of the sun itself. There is thus fortunately a sharp-cut line between these two efforts to advance our knowledge, and we hope that both bodies will ultimately find out the best ways of doing this. In a preliminary circular we read:—

The number of international organisations having considerably increased lately, it is desirable that overlapping of the work of different organisations should be avoided as much as possible. As far as solar research is concerned, a committee on questions dealing with radiation and the connection of solar and terrestrial phenomena has been appointed by the International Meteorological Committee. It will probably be found advisable to omit for the present the investigation of the relation of the sun-spot cycle to meteorological phenomena from the programme of the union; but the question of the solar constant being of fundamental importance must form from the beginning an essential portion of its work. The astronomical and meteorological aspects of solar radiation are, however, very different, and there is no reason to doubt that some arrangement can be made by which the efforts of the Meteorological Committee and those of the Union on Solar Research may be united.

We have not yet received the official protocols of the Oxford meeting, but some points may be referred to. The meeting was well attended, the following foreign men of science being present:—Prof. K. Ångström, Acad. Sci. (Stockholm); Prof. A. Belopolski, Acad. Sci. (St. Petersburg); Fr. Cirera, Ast. Soc. of France; Cte. de la Baume Pluvinel, Ast. Soc. of France; Mr. H. Deslandres, Ast. Soc. of France; Prof. W. S. Eichelberger; Mr. Fabry, Physical Soc. of France; Mr. G. E. Hale, Nat. Acad. Sci. (Washington); Mr. Hansky, Acad. Sci. (St. Petersburg); Mr. J. Janssen, Acad. Sci. (France); Prof. W. H. Julius, Acad. Sci. (Amsterdam); Prof. H. Kayser, German Physical Soc.; Mr. Perot, Physical Soc. of France; Prof. E. Weiss, Internat. Assoc. Acad.; Prof. Wolfer.

Dr. Janssen was elected honorary president, and Sir Wm. Christie president, of the meeting.

Among the many resolutions passed were the following, laying down the principles which should be followed in the proposed cooperation:—

(1) Cooperation is desirable in the various branches of solar research such as visual and photographic observations of the solar surface, visual observations of prominences and observations of the solar atmosphere with spectroheliographs of various types.

(2) When an institution has collected and coordinated results from various sources, members of the union shall be requested to place their observations at the disposal of the said institution.

(3) In the case of investigations which have not yet been thus collected and coordinated, special committees specially nominated by the union shall be charged with the work of preparing and carrying out the needful cooperation.

(4) It is proposed forthwith to organise such cooperation in two branches of research:—

(*a*) The study of the spectra of sun-spots.

(*b*) The study of the records, by means of the H and K light, of the phenomena of the solar atmosphere.

(5) The committee lays special stress on the fact that, notwithstanding the obvious utility of cooperation in certain cases, individual initiative is the chief factor in a very large number. It is as much the duty of the union to encourage original researches as to promote cooperation.

Much time was spent in discussing the constitution of the union, and several committees were appointed. There were most interesting discussions on solar radiation, Prof. Angström describing his instrument which has now been taken as the standard, and we may add that as this subject is also dealt with by the International Meteorological Committee, Prof. Ångström has been appointed chairman of the committees appointed by both organisations. The executive is to consist of a committee with Prof. Schuster as chairman, and a "computing bureau" is suggested at Oxford in charge of Prof. Turner, which is to deal, if necessary, with classes of observations not already provided for.

The next meeting is to be held at Meudon in two years' time.

NOTES.

WE notice with much regret that Sir William Wharton, K.C.B., F.R.S., died at Cape Town on September 29 from enteric fever and pneumonia, at sixty-two years of age.

WE regret to see, in the *Athenaeum*, the announcement of the death, in his sixty-ninth year, of Dr. W. von Bezold, professor of physics and meteorology at the University of Berlin, and director of the German Meteorological Institute.

THE death is announced of Dr. A. H. Japp, author of a life of Thoreau, several works on natural history, and "Darwin and Darwinism."

THE International Congress on Tuberculosis was opened at Paris on Monday, October 2, by the President of the French Republic. Dr. Hérard, the president of the congress, gave an address on international medical congresses, and the services which they have rendered in the struggle against consumption. Addresses were then given by the foreign delegates, and by M. Loubet.

A REUTER message from Gothenburg reports that a severe shock of earthquake was felt on September 26, 1.30 p.m., at Lundby, in the island of Hisingen. Subterranean rumblings were heard, and the houses suddenly began to rock so violently that inner and outer walls were cracked. The disturbance lasted about a minute.

NEWS has been received from Samoa that a volcanic eruption occurred on the Samoan islands on the morning of August 21. The eruption was preceded by a violent earthquake shock, which destroyed a large number of buildings. During the eruption large masses of material were ejected, and for five days lava flowed over more than four miles of the surrounding country.

IT is officially reported that a case of cholera occurred in Berlin on September 23, the victim being a canal bargeman on one of the Berlin canal harbours.

THE provisional programme for the session 1905–6 has now been published by the Royal Geographical Society. The first meeting will be held on November 6, when an introductory address will be given by the president, Sir George T. Goldie, K.C.M.G., F.R.S. The paper for the evening will be "Travels in the Mountains of Central Japan," by the Rev. Walter Weston. On November 20 the paper will be "First Exploration of the Hoh-Lumba and Lobson Glaciers (Himalaya)," by Mrs. Fanny Bullock Workman; on December 4, "Exploration in the Abai Basin, Abyssinia," by Mr. H. Weld Blundell; and on December 18, "Exploration in New Guinea," by Mr. C. G. Seligman. Other provisional arrangements include the following papers:—Colonel Sir T. H. Holdich, K.C.M.G., will deal with "Unexplored India"; Prof. J. W. Gregory, F.R.S., takes up "The Economic Geography of Australia"; Baron Erland Nordenskjöld will lecture on "Explorations in Bolivia and Peru"; and Prof. Alleyne Ireland on "The Philippine Islands." Mr. G. F. Scott Elliot will read a paper on "The Geographical Influences of Water Plants in Chile," and Mr. Laurence Gomme on "Maps of London." In the research department, Sir Clements R. Markham, K.C.B., F.R.S., will lecture on the subject "On the Next Great Arctic Discovery: the Beaufort Sea." In this lecture Sir Clements Markham will advocate detailed investigation of the unknown region lying between Prince Patrick Island and the New Siberian Islands.

THE Bureau of the Government Laboratories of the Interior has issued a Bulletin (No. 25) containing two articles by Mr. R. C. McGregor on birds from various islands of the Philippine group. Several species are described as new, among the most interesting of which is perhaps a new owl of the genus Otus. Illustrations are given of the enormous nesting-mounds of the Philippine megapode and of the nests and eggs of three remarkable species of swifts from the archipelago.

THE contents of the *Zoologist* for September include an illustrated article by Mr. R. B. Lodge on birds nesting in Andalusia (in the course of which allusion is made to the devastation among the bird-fauna caused by the late drought), and the second instalment of the editor's essay on extermination. Much interesting information will be found in the latter with regard to the destruction of animals caused in different parts of the world by floods, drought, pestilence, &c.

BIRDS obtained from the islands lying between Kiushu and Formosa form the subject of an illustrated paper communicated by Mr. M. Ogawa to vol. v., part iv., of *Annotationes Zoologicae Japonenses*. Coloured plates are given of a Garrulus, a woodpecker, and a heron of the genus Nannocnus, described as new. Special interest attaches to the description, by Mr. H. Sauter, of a riband-like fish from the Sagami Sea regarded as indicating a new genus and species (*Ijimaia dofleini*) of the small and peculiar family which the author considers to be typified by the Japanese and Indian Ateleopus, the new genus being characterised by the subterminal mouth and short ventral fins.

THE mutual affinities of the species of cray-fishes of the genus Cambarus forms the title of the only biological paper in No. 180 of the *Proceedings of the American Philosophical Society*. The author, Dr. A. E. Ortmann, finds that the commonly accepted division of the genus into five groups is not based on natural affinities, which has led to some erroneous conclusions with regard to geographical distribution. Observations on columbium and tantalum, by Mr. E. F. Smith, and an inquiry into the pressure and rainfall conditions of the trades monsoon area, by Mr. W. L. Dallas, are the titles of other articles.

THE entomological collection of the natural history branch of the British Museum will shortly be augmented by the collection of beetles bequeathed by the late Mr. Alexander Fry, which has been already deposited in the building. It is reported to be the finest collection of its kind in the country, and although not especially rich in types, contains an unrivalled series of weevils and longicorns. The total number of species in the collection is reported to be about 72,000, represented by some 200,000 specimens, many of these species being new to the museum. The cabinet includes the collections made by the late Mr. John Whitehead in Borneo and by Mr. W. Doherty in the Malay Archipelago generally. The bequest also includes a number of valuable entomological books. It may be mentioned that the collection of domesticated animals in the north hall of the museum has been recently enriched by the gift of statuettes of two famous racehorses, namely, "Persimmon," the property of His Majesty the King, and his son "Zinfandel," owned by Lord Howard de Walden; H.R.H. the Prince of Wales being the donor of the one and Lord Howard de Walden of the other.

THE fourth part of the thirty-third and the first part of the thirty-fourth volume of Gegenbaur's *Morphologisches Jahrbuch* contain an exceedingly interesting and important article on the papillary ridges and grooves on

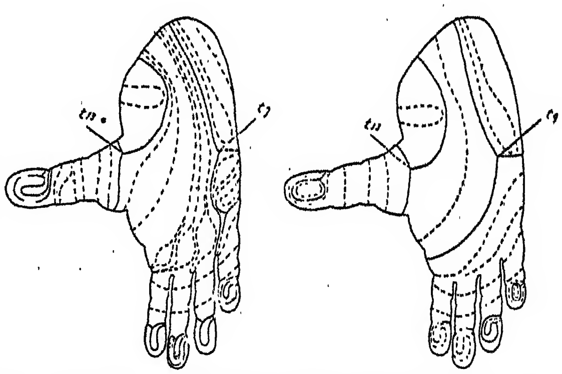

FIG. 1.—Two examples of the plantar surface of the right hind-foot of the chimpanzee to exhibit, in a diagrammatic manner, the "triradius" (*tr*). After Schlaginhaufen.

the sole of the foot in the Primates (inclusive of man), with especial reference to their serial correspondence with those of the palm of the hand, which have already been fully worked out by Hepburn and others. The article, which is by Dr. O. Schlaginhaufen, is far too long to permit of even a *précis* of its contents being given in this place, but it may be mentioned that the general arrangement of the papillary tuberosities is the same on the sole as on the palm. The most generally interesting fact brought out by the author's investigations is that while in all the Old World Primates (inclusive of man) the ridges and grooves on the sole in the neighbourhood of the great toe, or pollex, are so arranged as to form a triradiate system, termed the triradius, this feature is totally wanting in the monkeys of the New World. We have thus a new and deep-seated distinction between "Catarhini" and "Platyrhini."

AMONG the contents of the latest parts of the *Morphologisches Jahrbuch* (vol. xxxiii., part iv., and vol. xxxiv., part i.) may be mentioned an article by Mr. E. Göppert on the brachial artery of the Australian spiny anteater (Echidna), with special reference to the arterial system in the fore-limb of mammals in general, and a second, by Dr. O. Grosser, on the existence of a distinct segmental arrangement in the superficial vascular system of the human chest. In the second of the two volumes Dr. E. Küster describes the so-called *tastfeder* (sensory feathers) found at the base of the beak in owls and other birds, which are shown to be provided with sensory corpuscles, and are correlated by the author with the "feelers" or vibrissæ of mammals.

ALL the articles in the two concluding parts (iii. and iv.) of vol. lxxix. of the *Zeitschrift für wissenschaftliche Zoologie* deal with the anatomy and development of invertebrates. The minute structure of the eye receives the attention of two writers, Mr. H. Merton discussing the retina in nautilus and other dibranchiate cephalopods, while Mr. M. Nowikoff describes the eye and frontal organs of the branchiopod crustaceans. The spermatozoa of the common intestinal round-worm (Ascaris) receive attention at the hands of Mr. L. Scheben, of Marburg, Mr. K. Thon treats of the excretory organs of the hydrachnid family Limnocharidæ, while Mr. Stoffenbrink records the effects of special nutrition on the histological constituents of the fresh-water planarians. Finally, Mr. A. Zwack discusses the minute structure and mode of formation of the "ephippium" of the fresh-water flea (Daphnia), while Dr. E. Martini devotes himself to observations on the amœba-like Arcella.

THE latest number of *l'Anthropologie* (vol. xvi., No. 3) contains a useful article on Paumotu fishing implements. The British Museum is singularly poor in specimens from these islands, and the "Album" of Edge-Partington and Heape only figures two or three fish-hooks. In the present article a dozen hooks are figured and described; the construction of the canoes and method of sewing the planks are also illustrated. An article on the musical instruments in French Congo is diminished in value by errors in the illustrations; the *bambour* on p. 289 is reproduced from a sketch, and the artist has omitted the pins to which the strings are attached, making it appear that there is no means of altering the tension of the cords.

THE Department of Agriculture in Jamaica has been at considerable trouble to effect the improvement of home-grown tobacco, and if the experiments carried out at Hope Gardens may be taken as a criterion, there is a promising future for Sumatra wrapper-tobacco grown in the open and for Havana leaf, both shade-grown for wrapper and outside-grown for filling.

THE South Orkney Islands, lying about 600 miles south-east of Cape Horn, were visited by members of the Scottish National Antarctic Expedition voyaging in the ship *Scotia* in February, 1903. The collections of mosses and lichens obtained by Mr. R. N. R. Brown, the botanist of the expedition, are described in vol. xxiii., part i., of the *Transactions and Proceedings of the Botanical Society of Edinburgh*. Mr. C. H. Wright has identified six mosses which are all Antarctic, except one previously known only from Tristan da Cunha. Dr. O. V. Darbishire has worked out the lichens and distinguishes twelve species, including one, *Placodium fruticulosum*, new to science.

THE explanation that plants have developed thorns to keep off the depredations of herbivorous animals does not lend itself to experimental investigation, as the development would be an exceedingly slow process. But the argument that thorns are merely xerophytic structures is more easily put to the test, and Dr. L. Cockayne describes in the *New Phytologist* (April) his experiments with the New Zealand shrub *Discaria Toumatou*, known popularly as Wild Irishman, which in ordinary circumstances is abundantly furnished with long pungent spines. The experiments consisted in removing plants, at the stage when spines were beginning to be formed, to a moist chamber, where they were grown, and there maintained the leafy spineless habit characteristic of seedlings.

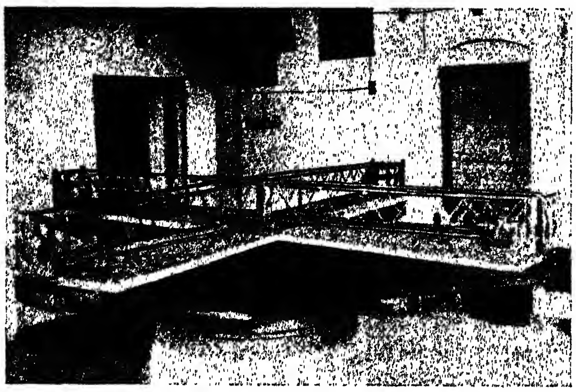
THE investigations of Prof. G. Haberlandt on the sense-organs of plants, which are of great scientific interest, form a suitable subject for popular exposition, and an account by Mr. G. C. Nuttall appears in the *Monthly Review* (September). The main result of Prof. Haberlandt's work was to show that where plants are sensitive to touch, at these points special adaptations of hairs or cells are found. The sensitiveness of tendrils and of the specialised leaves of Drosera and Dionæa is a matter of common knowledge, but the irritability of the stamens of such plants as Opuntia, the prickly pear, and Abutilon is less generally known. At certain spots the stamens of these plants are provided with papillæ which enable them to perceive contact stimuli. The concluding argument which is presented to the reader that plants are capable of experiencing sensations is by no means convincing.

THE German Meteorological Institute, of which the late Prof. v. Bezold was director, has published a second edition of its very useful "Instructions for Taking and Reducing Meteorological Observations." A great part of the work (as the title indicates) has been re-written and re-arranged to bring it up to date as regards the improvements in methods and instruments that have taken place in recent years. The work is divided into two volumes, dealing (1) with the requirements of stations of the second and third orders, and (2) with special observations and instruments; the latter part contains valuable explanations of the principles and adjustments of Richard's much used self-recording apparatus, of anemometers, sunshine recorders, and the nephoscope, all of which it is most essential that observers should thoroughly understand, but which are not always to be found in existing instructions. The aim of the work is to instruct observers in all parts of the operations required of them, from the choice of a suitable locality for a station, the erection of the instruments, and the method of taking observations, to the deduction of mean results, the most essential portions being printed in larger type. The work will certainly fulfil the intention of its author, viz. to render lighter the labours of observers and to ensure accuracy in their observations and calculations.

IN the *Memorie* of the Royal Institute of Lombardy (vol. xx.) Dr. Alessandri gives an account of the Regina Margherita Observatory at the summit of Monte Rosa, on the peak known as the "Signalkuppe," 4559 metres above sea-level. The station is under the control of the Central Meteorological Office at Rome, and it is intended (if possible) that observations should be made each year between July 15 and September 15. The difficulties encountered in the first year (1904) were so great that Dr. Alessandri states that the expedition can only be considered as a preliminary attempt, with the view of overcoming them in future years. The conveyance of instruments and materials from Alagna had partly to be done by mules and partly by men, at a cost of 62 centesimi for each kilogram

(2.2 pounds' weight), with the result that many of the instruments were broken in transit. Owing to the intense cold, the clogging of the apparatus by hoar-frost and violent snowstorms, together with the intense electrification of the atmosphere, rendered regular observations almost impossible with the means then available. The shade air-temperature at the summit of Monte Rosa is practically always below freezing point; the thermometers taken by Dr. Alessandri read to $-20°$ C., but the extreme temperature often fell below that. The mean reading of the barometer during the summer of 1904 was 17·1 inches; water therefore boiled at about 85° C. The lightning conductors frequently appeared like steadily burning candles, and the observers experienced at times such unpleasant shocks that it became advisable to retire within the observatory.

ABOUT twenty years ago Messrs. Michelson and Morley concluded from the results of their well known experiments that the ether in the neighbourhood of the earth is not at rest in space, but is carried along with the earth in its motion. Prof. Fitzgerald and Prof. Lorentz subsequently suggested that the experimental results of Michelson and Morley might also be explained by the dimensions of the apparatus being modified by its motion through the ether. In order to test this assumption, Messrs. E. W. Morley and D. C. Miller (*Proceedings Amer. Acad. Arts and Sciences*, xli., No. 12) have repeated on a more elaborate



scale the experiments of 1887, using two modified forms of apparatus. The sandstone of the earlier experiments was replaced in one form of apparatus by a structure of white pine, whilst in the final and more complete experiments a steel framework was used to support a system of pine rods. The figure shows the steel cross-framework adopted, with the trusses supporting the distance pieces and the mirror frames and telescopes in position. The entire apparatus weighed 1900 lb., and floated in mercury. As a result of the experiments, a nearly similar conclusion to that previously formed is arrived at. If the dimensions of the pine are changed, the change is of the same amount as with sandstone; if the ether near the apparatus did not move with it, the difference in velocity is apparently less than 3·5 kilometres per second.

THE *Journal of the Royal Sanitary Institute* for September (xxvi., No. 8) contains an important paper by Prof. Woodhead on the water supply problem in rural districts, together with the discussion thereon.

IN the *Century Illustrated Monthly Magazine* for October Prof. Chittenden gives a popular account of his researches on the amount of nitrogenous food required to maintain physiological equilibrium, which, should his results stand the test of time, will mean great economy in the future. General Horace Porter writes a graphic account of the investigations which led to the search for the body of Paul Jones and its ultimate recovery in the forgotten cemetery of Saint Louis, its identification, and removal to the United States.

WE have received the results of meteorological observations for 1900–2, and of rain, river, and evaporation observations for 1901–2, made in New South Wales. The latter work contains valuable statistics of rainfall for each month for the years in question, and various returns for other periods, *e.g.* the mean annual rainfall at all stations with three and up to fourteen years' records from 1889 to 1902 inclusive, and records for the whole of Australia for individual years since 1840. In the years 1901–2 severe and almost unprecedented droughts were experienced. The average fall for the whole colony for thirty-two years (1871–1902) is 24.15 inches, but in 1901 the amount was only 18.15 inches, and in 1902 14·09 inches, the lowest average on record with the exception of that for the year 1888, when it was only 13·40 inches. The effect on sheep grazing was disastrous; the number of sheep in the western division during seven years ending with 1901 dwindled from about 16 millions to 5 millions, representing a loss to the State of about 30 millions sterling.

IN the current issue of the *Journal of the Franklin Institute* the first instalment is published of an elaborate monograph on mica by Mr. G. W. Colles. The subject is dealt with chiefly from an industrial point of view, the present, past, and probable future of mica mining being discussed.

A SECOND edition of the second volume—dealing with the chemistry of manufacturing processes—of "Chemistry for Engineers and Manufacturers," by Messrs. Bertram Blount and A. G. Bloxam, has been published by Messrs. Charles Griffin and Co., Ltd.

MR. OSCAR GUTTMANN, 12 Mark Lane, London, E.C., intends to publish a facsimile reproduction of all ancient pictures and engravings dispersed in libraries all over the world referring to the invention, early manufacture and examination, and first use of gunpowder. It is to be a work of art, printed by hand on the finest hand-made paper, with an imitation fifteenth century binding, and limited to about three hundred numbered copies.

WE have received from Messrs. J. J. Griffin and Sons, Ltd., 20–26 Sardinia Street, Lincoln's Inn Fields, W.C., their "T" list of thermometers and pyrometers for measuring temperatures between $-200°$ C. and 4000° C. The list is a fairly complete one, and comprises ordinary, technical, and standard thermometers, as well as the principal forms of electrical resistance, thermoelectric, and optical pyrometers.

MESSRS. PHILIP HARRIS AND CO., LTD., of Birmingham, have issued their diary intended for the use of teachers and others during the session 1905-6. A very complete calendar of the examinations to be held by the chief public examining bodies during the coming educational year is provided, and there are spaces for daily notes, general memoranda, addresses, and cash accounts.

WE have received from Messrs. Williams and Norgate a copy of a new work published by Herr H. A. Ludwig Degener, of Leipzig, entitled "Wer ist's?" The volume is similar in its scope to "Who's Who," and is edited by Herr H. A. L. Degener. In addition to the particulars given of distinguished Germans, the book also includes

biographies of famous living Austrians, Frenchmen, Englishmen, and celebrities of other nationalities. The Englishmen noticed in the volume appear to be politicians as a rule, and, so far as we have tested the book, the men of science and of letters selected for inclusion are neither numerous nor particularly representative.

WE have received from Messrs. W. M. J. Brooks and Co., Letchworth, Herts, a set of five templates, or curves, accurately cut in celluloid, representing respectively the parabola, ellipse, hyperbola, cycloid, and cubical parabola. When such curves are required it seems better that a student should make them for himself, but failing this Mr. Brooks's curves may prove useful in special cases. The price is 1s. each curve.

OUR ASTRONOMICAL COLUMN.

FURTHER RESULTS OBTAINED BY THE FRENCH ECLIPSE EXPEDITIONS.—In No. 12 (September 18) of the *Comptes rendus* MM. Deslandres and Andoyer give brief summaries of the results obtained by them on their respective expeditions to observe the recent total solar eclipse.

M. Deslandres directed the Bureau des Longitudes mission to Burgos, where the actual duration of visible "totality" was curtailed by clouds to one minute, which did not include either the second or the third contacts. The proposed photographing of the chromosphere spectrum was therefore impossible. Photometric observations of the corona were obtained, and M. d'Azambuja was able to measure the coronal radiation, obtaining figures which were decidedly lower than those obtained by M. Charbonneau in 1900. M. Kannapell obtained four photographs of the corona polarised by reflection. M. Blum obtained two photographs of the corona through coloured screens so arranged as to transmit only the gaseous radiation of the prominences. By comparing these with the ordinary photographs it will, probably, be possible to determine whether or not the prominences emit a more intense continuous spectrum than that emitted by the surrounding regions.

At El-Arrouch, 32 km. from Philippeville, M. Andoyer simply attempted to obtain as many direct photographs of the phenomena as possible. His instrumental equipment consisted of a photographic objective of 14 cm. (5·6-inch) aperture and 60 cm. (24-inch) focal length, mounted with two enlarging cameras which increased the diameter of the image by three and eight times respectively.

Altogether forty-four plates were exposed, eleven of them during totality. A negative exposed two minutes before totality shows a reversed image, due to over-exposure, and a silhouette of the corona.

ELEMENTS OF COMET 1886 VIII.—From eighty-six observations of comet 1886 viii., made by various observers between January 24 and May 20, 1887, Herr E. Fagerholm, of Upsala, has calculated a set of elements for the orbit of that object. These, as given below, appear in No. 4047 of the *Astronomische Nachrichten*, together with the details of the computation and of the planetary perturbations taken into account:—

$$T = 1886 \text{ Nov. } 28{\cdot}44284 \pm 0{\cdot}00267 \text{ (M.T. Berlin).}$$

$$\left.\begin{aligned} \omega &= 31^\circ\ 55'\ 34''{\cdot}53 \pm 18''{\cdot}25 \\ \Omega &= 258^\circ\ 13'\ 1''{\cdot}35 \pm 4''{\cdot}43 \\ i &= 85^\circ\ 35'\ 17''{\cdot}33 \pm 3''{\cdot}84 \end{aligned}\right\} 1887{\cdot}0$$

$$\log q = 0{\cdot}1704712 \pm 0{\cdot}0000214$$

THE FIGURE OF THE SUN.—In No. 2, vol. xxii., of the *Astrophysical Journal*, Mr. C. Lane Poor publishes the results of an investigation, carried out by him at the Columbia University Observatory, which seem to indicate a periodical variation in the figure of the sun agreeing in phase with the sun-spot curve. On measuring the equatorial and the polar diameters of the solar images on twenty-one plates taken by Mr. Rutherfurd in 1870, 1871, and 1872, he found indications that during this period the equatorial diameter was first increasing and then decreasing with regard to the polar diameter. To check this result he re-investigated the measures made by the German observers whilst adjusting, and determining the constants of, their heliometers for the transits of Venus in 1874 and 1882. The 1873–5 results showed a progressive change similar to that indicated by the measures of the Rutherfurd photographs taken in 1871–2, whilst the 1880–3 heliometer measures confirmed the photographic results of 1870–1. Yet another confirmation was found on measuring five solar negatives taken at Northfield (Minn., U.S.A.) during the years 1893–4, the change in figure being the same as in 1871–2 and 1873–5.

Plotting the differences between the polar and equatorial diameters in conjunction with the sun-spot curve, it is seen that the two agree, not only in point of time, but also of intensity, the excess of the equatorial diameter occurring at sun-spot maximum.

From these results it appears that the sun is usually an oblate spheroid, but at times of sun-spot minima the length of the polar axis increases in regard to that of the equatorial diameter, and the solar figure becomes prolate.

Mr. Lane Poor incidentally suggests that this variation of the solar figure may explain the anomalies in the motions of Mercury, Venus, and Mars.

BIBLIOGRAPHY OF HALLEY.—No. 14 of the Bulletin of Bibliography Pamphlets, issued by The Boston Book Company, contains the material for a bibliography of Dr. Edmond Halley, the second Astronomer Royal, and will be found a useful adjunct to any astronomical library. Reading through the numerous items, one is struck anew by the range and number of Halley's writings. The pamphlet is an extract from No. 4 (July), vol. iv., of the Bulletin of Bibliography published by The Boston Book Company, and costs 25 cents.

OBSERVATIONS OF JUPITER'S SATELLITES.—In No. 4045 of the *Astronomische Nachrichten* Profs. A. A. Nijland and J. van d. Bilt publish the results obtained from a large number of observations of Jupiter's satellites.

These observations were made with the 26 cm. Utrecht refractor during the period June 30, 1904–February 17, 1905, and in the tabulated results the time of the eclipse, transit or occultation of the particular moon is given, together with the difference between these and the calculated times.

A LOST DOUBLE STAR.—A remarkable chapter of coincidences is recorded in No. 7, vol. xiii., of *Popular Astronomy* by Prof. Doolittle, of the Flower Observatory, U.S.A. In Sir John Herschel's first catalogue of double stars, No. 165 was described as a 3″ pair with a position angle of 330°, its position being given as R.A. = 10h. 26·8m., dec. = +12° 32′ (1825). In 1878 Prof. Burnham directed his attention to the pair, and recorded its position angle as 205°·3, and its distance as 2″·59. Again in 1901 he observed the double with the 40-inch refractor, and obtained a measure agreeing with Herschel's record; but in 1902 he could find no trace of the pair observed in the previous year, nor of the star measured by him in 1878. Observations made this year with the 18-inch refractor of the Flower Observatory failed to reveal the double given by Herschel, but showed a very wide faint pair in the exact position given by him.

Thinking that Prof. Burnham in 1901 might have confused the sign of the declination, Prof. Doolittle turned his telescope to the same R.A. in declination *minus* 12°, and there apparently found exactly the pair that was wanted. This seemed to have cleared up the mystery; Prof. Burnham had in 1901 observed the wrong star.

A letter from that observer showed, however, that this is not the correct explanation.

The truth is that Herschel made a mistake of exactly one hour in recording the right ascension of H. 165, and Prof. Burnham had, unwittingly, made precisely the same mistake in 1901. Thus the latest observation of Herschel's No. 165 shows its position to be R.A. = 9h. 31m. 13s., dec. = +12° 25′ (1880), and its position angle and distance, at the epoch 1905·38, were 333°·1 and 2″·04 respectively.

In 1878 Prof. Burnham, observing in the position given by Herschel, saw a pair which was not identical with H. 165, and in the year 1902 was too faint for him to see. In 1901, repeating Herschel's mistake in the R.A., he observed the true H. 165, whilst in 1905 Prof. Doolittle found a similar pair to H. 165 in the same declination *south* and in the R.A. given in mistake by Herschel.

TYPE-WRITING BY TELEGRAPH.[1]

ONE of the most interesting papers read during the last session of the Institution of Electrical Engineers was that by Mr. Donald Murray on setting type by telegraph. Strictly speaking, the title of the paper is something of a misnomer, as the apparatus described by Mr. Murray was constructed for type-writing rather than type-setting; but as the principle is equally applicable to the latter process, it is unnecessary to be too critical. This is specially the case as the instruments and method were originally designed for the automatic telegraphic operation of linotype machines, and it was only because commercial considerations indicated the greater importance of the solution of the problem of telegraphic type-writing that attention was more particularly devoted to this question.

FIG. 1.—Keyboard Perforator with cover removed.

The problem which has to be solved is one of considerable complexity, as will readily be realised when its essential characteristics are considered. A message handed in at the transmitting station has to be translated into a series of signals which can be telegraphically transmitted over a single telegraph wire. These signals, on arriving at the receiving station, must actuate a receiving mechanism in such a manner that a particular set of signals produces a certain definite movement of the mechanism; thus the signals corresponding to the letter "a" must cause the striking (or equivalent) of the type-writer key "a," the signals corresponding to a notification of the end of a line must cause the shifting of the type-writer carriage ready for a new line, and so on. Now it is obvious that the signals as they are transmitted over the telegraph wire can only differ from each other by virtue either of their time arrangement or their magnitude. Each set of signals (corresponding to a letter) must be made up of one or more pulses of current, and one letter can only be distinguished from another by virtue of the pulses for the one being different in magnitude from those for the other, by their following one another at different intervals of time, or by their lasting for different periods of time; of course, also, a combination of any two or of all three of these may be used. It is not possible for the telegraphic signals to be differentiated in space unless more than one wire is used to connect the two stations. It is equally clear that the distinction between the signals in their final form is one of space, and this is so whether we consider the ultimate result, that is to say, the printed letter, or merely the alterations produced in the space relationship of the various parts of the printing mechanism which causes that mechanism instantaneously to print a particular letter. Thus we may say that what a type-writing telegraph has to do is the following:—it has to receive a message and translate it into a series of time or magnitude signals, to transmit these signals electrically over a wire, and to re-translate them into a series of space signals.

We have had occasion during recent years to describe several systems of telegraphy which aim at doing much the same thing as the Murray telegraph attempts, and it is of interest to compare the transmission methods used in these. Thus in the telautograph (see NATURE, vol. lxiv. p. 107) the actual handwriting of the original message is transmitted and reproduced, and this is done by a combination of space and magnitude signals. Two wires are used, and current pulses of varying magnitudes sent along them which reproduce at the receiving end the motion of a pen at the transmitting station. Here the time element of the signals has no effect, and a letter is reproduced equally if it be traced in one second or in one hour. In the Pollak-Virag system (see NATURE, vol. lxiv. p. 7) the telegraphic signals produce the motion of a beam of light which records in Roman letters the message transmitted. In this system the telegraphic signals differ from one another in their space relation and their duration. In the Murray system the signals differ from one another in their time relation.

We have pointed out that the first process is the translation of the message into a series of time signals, and for this purpose a time signal alphabet has to be chosen. Though this may at first sight seem a matter of secondary importance, it is in reality hardly too much to say that upon the suitability of the alphabet selected will depend, more than upon anything else, the chances of success of the system. This fact has been thoroughly realised by Mr. Murray and others who have worked upon this problem, with the result that an alphabet has been finally devised which seems to possess in the greatest degree possible all the more important advantages. In it every letter or other signal which has to be transmitted is represented by a series of five time signals; the alphabet is therefore an "equal letter alphabet," that is to say, each letter is composed of the same number of signal units (five in this case). The average number of units per letter is, of

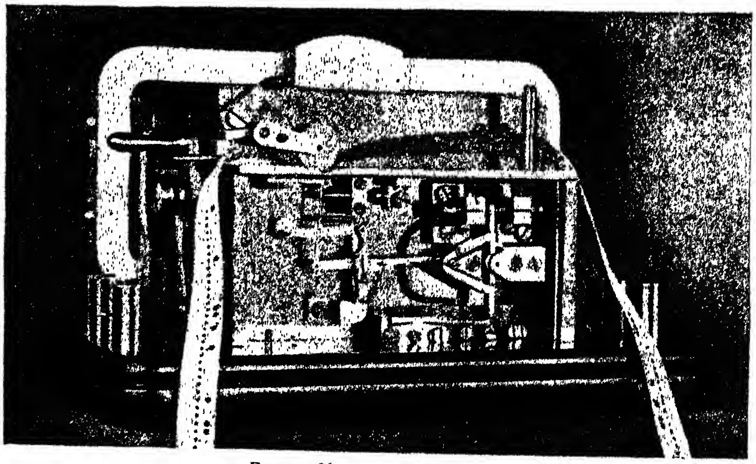


FIG. 2.—Single-line Transmitter.

[1] "Setting Type by Telegraph." By Donald Murray. (*Journal of the Institution of Electrical Engineers*, vol. xxxiv., pp. 555. 1905).

course, five; in the Morse alphabet the average number is thirteen; there is therefore an apparent advantage in time over the Morse code, but this may be more apparent than real, as the unequal length of the letters in the Morse code enables the shorter ones to be chosen for those letters occurring with the greatest frequency (such as E and T), so that the average number of units per message may be less than in an equal letter alphabet having a smaller average number of units per letter. Thus experience has shown that the actual average number of units per letter with the Morse code is only eight instead of thirteen. It must be remembered, also, that the Morse code is intended primarily for hand signalling, and consequently when time intervals are used the difference between any two which have to be distinguished manually or by ear must be fairly great. Thus the Morse dot consists of one unit, the Morse dash of three; were two units used for the dash instead of three, the distinction between the dash and dot would not be sufficiently marked. With machine telegraphy, on the other hand, there is no need to make such a great differentiation between the signals, as time intervals of one, two, three, and more units can all be distinguished, and in consequence it is possible to devise a shorter alphabet than the Morse code. It is not to be denied, however, that the use of a new alphabet is undoubtedly a disadvantage from the practical point of view, as it has to be learnt by the operators. This drawback is minimised by the fact that the operator does not print each signal separately as in operating a transmitting key; but it is nevertheless desirable, if not essential, that he should be able to read the message when printed on the transmitting tape.

To turn now to the apparatus used in the Murray system; the first operation, as in all automatic telegraph systems, is to punch the message to be transmitted on a paper strip or "tape." This is done by means of a key-board instrument of the ordinary type-writer form shown, with the cover removed, in Fig. 1. On the tape will be noticed a double row of holes, which can be seen more distinctly in Fig. 4; the row of small holes serves only to feed the tape forward, both in this machine and in the transmitter; the larger holes are the signals punched in the tape. The actual perforator can be seen in front; it is worked by an electromagnet which punches the necessary holes on the forward stroke and moves the tape one letter space (five holes) forward on its back stroke. On the right can be seen a lever which enables the tape to be pulled back letter by letter to make corrections; these are made by punching five holes, thus blotting out all the holes already punched, this signal (of five holes) leaving the receiving mechanism unaffected. It is thus possible to wipe out any part of the message incorrectly written on the tape, and so produce a tape which will give an absolutely correct message when transmitted; this is facilitated by the fact that the operator can see the tape as it is perforated, letter by letter. The speed at which this perforator can be worked is about 120 letters (twenty words) a minute. The transmission can be carried on five or six times as rapidly, so that five or six operators working at these perforators can produce enough tape to keep the transmission line full.

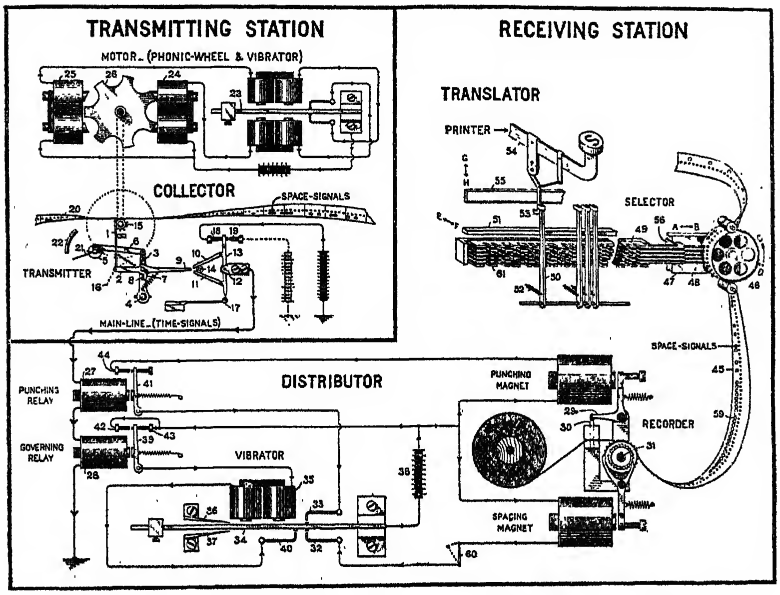

FIG. 3.—General Diagram of Murray Automatic Printing Telegraph System.

The automatic transmitter is shown in Fig. 2, and diagrammatically in Fig. 3 (collector). The tape is fed forward in the usual way by the star-wheel 15, passing across the end of an upright rod 1. This rod is pivoted as shown to the system of levers which oscillate about the centre 4, being kept in oscillation by the eccentric wheel 5, and making one oscillation for every unit on the tape. If this unit is a hole, the rod 1 enters this hole, the end 2 of the lever 2-9 is raised and the end 9 lowered, whereby the oscillation of the lever 3 brings the end 9 against the bar 11, thus pushing the contact lever 13 against contact 18. Here it remains until the next oscillation, and if this is the same as before, due to a second hole in the tape, it is not disturbed. It will thus be seen that successive signals of the same kind (either successive holes or successive spaces) are transmitted, not as intermittent, but as continuous signals. But if there follows a space in the tape the rod 1 cannot rise to its full height, the lever 2-9 is kept down at the end 2 and raised at the end 9, which comes in consequence against the rod 10 and forces the contact lever 13 over against contact 19, thereby breaking the punching current and sending spacing current into the line. The whole apparatus is driven by a phonic wheel motor in the usual way, the vibrating reed 23 sending currents alternately to the magnets 24 and 25, which keep the armature 26 in rotation. This is geared directly to the star-wheel 15, which has ten teeth, and is itself geared in the ratio of 10 : 1 to the eccentric wheel 5, so that the latter makes, as already stated, one revolution for every unit of the tape.

Now let us follow the message to its arrival at the receiving station, where the signals are caused to produce a second perforated tape, the exact duplicate of the first, by means of the mechanism grouped together in Fig. 3 under the title "distributor." The tape is fed forward unit by unit by means of the spacing magnet which operates the escapement 31, and holes are punched in the

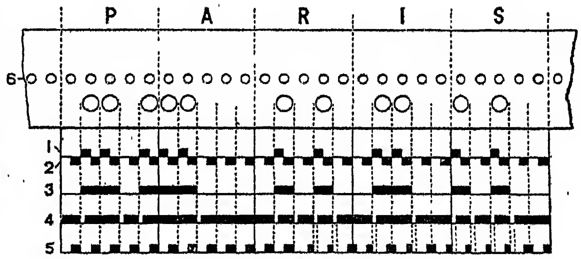

FIG. 4.

tape by the punch 30, which is operated by the punching magnet. If the circuits of these two magnets are followed out it will be seen that both are controlled by the vibrating reed 34 in such a way that they operate alternately according as the reed is against contact 32 or 33. It will further be seen that the punching magnet is also controlled by the punching relay 27, the circuit being open in the position shown, and closed when the reed 41 is against contact 44, *i.e.* when punching current is coming through the main line and punching relay. It will be noticed at once that the distributor cannot work properly unless the tongue 41 of the punching relay is in synchronism with the reed 34. To obtain this synchonism is the object of the governing relay 28, which is operated by the line current. The tongue of this relay vibrates between the contacts 42 and 43; when it is in contact with either the circuit of the vibrator magnet is closed, but during its passage from one to the other this circuit is opened. If this occurs whilst the contact 40 is open it can obviously have no effect on the oscillations of the reed, but if it occurs whilst this contact is closed it has the effect of diminishing the duration of the current in the vibrator magnet. The reed 34 vibrates against two springs 36 and 37, so that its time of vibration is capable of great control by the magnitude of the current in the vibrating magnet. By setting it so that its natural speed is a little too high, it is possible by means of the controlling action of the governing relay for perfect synchronism to be obtained. The action will perhaps be more readily understood by the diagram, Fig. 4. This shows a piece of the transmitting tape at the top punched with the signals for the word "Paris." In line 1 are shown the current impulses to the punching magnet due to the simultaneous closing of contacts 33 and 44. In line 2 are the regular intermittent current impulses to the spacing magnet due to the closing of contact 32. Line 3 shows the main line signals which, as pointed out in explaining the method in which the transmitter acts, are continuous and not intermittent. Line 4 shows the interruptions in the circuit of the vibrator magnet caused by the vibration of the reed of the governing relay which occurs at the beginning and end of every signal in line 3. In line 5 are the actual current pulses in the vibrator magnet due to the closing of contact 40. These are shown in step at the beginning, but gradually falling out of step, whereby, as will be seen, they are diminished by the interruptions shown in line 4, and are thus automatically brought back into step.

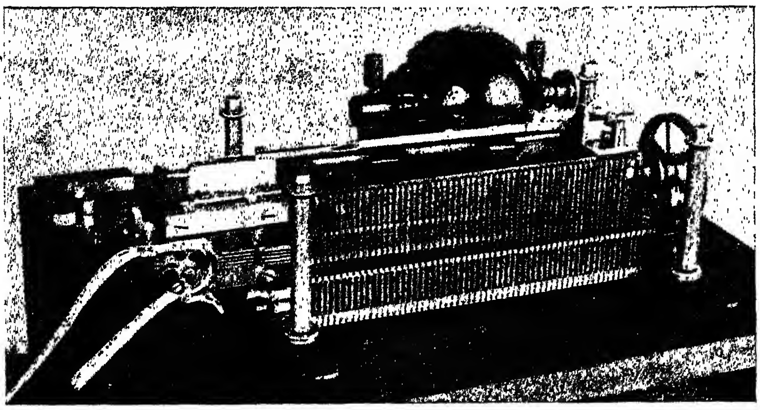

FIG. 5.—Murray Printer with Typewriter removed.

The only remaining operation is to use the tape 45 (Fig. 3) to work either a type-writer or a type-setting machine. The Murray printer with the type-writer removed is shown in Fig. 5, and diagrammatically in Fig. 3. It will not be necessary to describe it in detail; the principle is that of the ordinary lock and key. The tape is fed forward letter by letter by means of the star-wheel 46; the reciprocating shuttle 47 carries a die-block, which allows the five rods 48 to pass through the perforations in the tape when these are present. According as one or more of these rods passes through the tape, a particular set of slots in the combs, 49, attached to the rods is brought into line, the corresponding lever 50 is pulled into the channel thus formed, and the corresponding type-writer key is depressed.

The complete set of Murray apparatus is shown in Fig. 6. On the extreme right is the perforator, next to it on the left the automatic transmitter, then on the same table the distributor in front and the relays behind. The translator and type-writer are on the small table at the left. We have only been able to give a brief description of the most important features of this very ingenious system; there are numerous points of detail which space does not permit us to describe. The system has been on trial for some time both in this country and abroad, and has met with considerable success; it is now in use on several English lines. There can be no question after the perusal of Mr. Murray's paper that it possesses many advantages over its forerunners which should enable it to survive. It is stated that the automatic part of the apparatus can be run perfectly up to 200 words (1200 letters) a minute, but that no type-writer will stand the strain of being run at this speed, a maximum of 120 words being all that is allowable. It is, however, obviously possible to run the automatic part at top speed if necessary, and use two type-writers at the receiving end in the same way as at the transmitting end.

MAURICE SOLOMON.

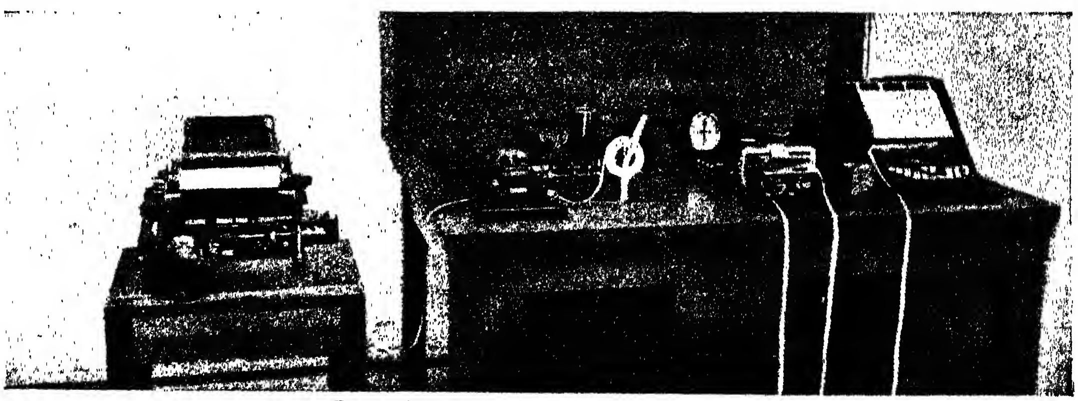

FIG. 6.—General View of a Set of Murray Apparatus.

THE PERCY SLADEN EXPEDITION IN H.M.S. SEALARK. THE CHAGOS ARCHIPELAGO.

OUR arrival in Mauritius on August 5 completed the first half of our cruise in H.M.S. *Sealark*, together with all our work directly connected with the Chagos Archipelago. This work may be divided under two heads, oceanography and biology. The former has been carried out mainly by Commander Boyle Somerville and his officers in view of the scientific objects of the expedition, but at the same time it is all of practical value for navigation in these waters. In many respects it has been of a singularly arduous nature; surveys by camping parties and deep soundings from the ship have been carried on simultaneously, together with numerous observations on the tides, currents, sea temperatures, &c. To a considerable degree it and all the work has been hampered by the heavy weather, which, contrary to all expectation, we have experienced, winds from south to east with heavy, confused seas, partially induced by the comparatively shallow waters of the Chagos Archipelago, and partially due to the current, which set in an easterly direction (against the wind) during the whole time we were in the group.

It is almost too soon to attempt to summarise any of the results of the cruise, but the soundings taken on our course from Ceylon to the Chagos and from the latter to Mauritius show that the archipelago is closely surrounded, both to the north and west, by the 2000-fathom line, and that there is at the present day no trace in the topography of the Indian Ocean of any former connection of the group with either the Maldives or the banks on the Seychelles-Mauritius line. The Chagos Archipelago appears, indeed, to stand by itself, being built up on a plateau rising to a depth of 800 fathoms in an ocean of an average depth of 2300 fathoms. Previously there were no bottom soundings between the banks and shoals of the group, but now a large series (more than 100) have been run, showing depths of 400 fathoms to 800 fathoms between the individual banks; from most of these a sample of the bottom has been obtained.

Broadly speaking, the Chagos group may be said to consist of three atolls to the north (Salomon, Peros Banhos, and Blenheim), the Great Chagos Bank in the centre (60 miles by 90 miles), and to the south two atolls, Diego Garcia and Egmont, besides certain submerged banks both to the north and south. Of these, H.M.S. *Sealark* has re-charted Salomon and parts of Peros Banhos, while Cooper and I have in addition examined the southern atolls. Salomon was very carefully surveyed, our intention being to make a comparison between its condition at the present time and when Powell's chart was made in 1837. The latter chart, however, proved to have been so carelessly drawn that any close comparison is, I fear, useless, but the new chart should be of great value when it is possible to re-examine the atoll at some future date. Its section lines show that it arises in the last 400 fathoms by similar slopes to those of Funafuti, but it is a much simpler atoll, having only one passage, and more than half its reef crowned by land. Our numerous soundings and dredgings on its slopes leave no room for doubt but that its present reef is extending outwards on every side on its own talus, in fact, that the steep found round it (and, indeed, most atolls) is, *in this instance*, simply the slope at which coral and other remains from the reef above come to rest in the water. Its face was everywhere singularly barren; Lithothamnion, Polytrema, and, of course, reef-corals were not obtained below 50 fathoms. Further out, at 250 fathoms and over, the bottom was smooth and barren; the lead constantly failed to bring up any samples, while the somewhat broken and dented, but almost empty, dredges gave the idea of bare rock with a little muddy sand here and there. Indeed, our evidence points to the impossibility of any upward growth being in progress between the different Chagos banks, and to the probability of considerable current being felt even at 500 fathoms.

The reefs of the Chagos are in no way peculiar save in their extraordinary paucity of animal life, to which I referred in my last letter. Green weed, too, of every sort is practically absent. However, this barrenness is amply compensated for by the enormous quantity of nullipores (Lithothamnia, &c.), incrusting, massive, mammillated, columnar, and branching. The outgrowing seaward edges of the reefs are practically formed by their growths, and it is not too much to say that were it not for the abundance and large masses of these organisms there would be no atolls with surface reefs, &c., in the Chagos. The lagoon shoals of Egmont are covered by them, and alone reach the surface; having once done so they die and become hollowed out in the centre, finally resembling miniature atolls.

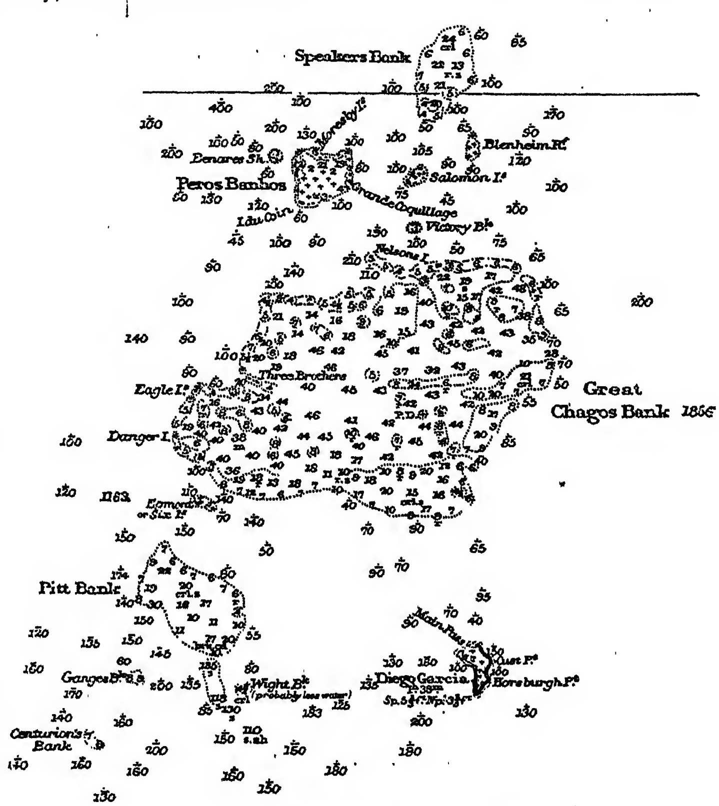

FIG. 1.—Chart of the Chagos Archipelago.

In such a large group the conditions of the encircling reefs against the lagoons naturally vary very considerably. In general their inner edges reach the surface, and in the more open atolls the lagoon slope to 10 fathoms closely resembles the seaward slope. The bottoms of the lagoons are bare, rock, hard sand or mud, with shoals arising precipitously here and there, built up by a few species of coral, but largely covered by Xenia and Sarcophytum (as also are the only two submerged banks, Wight and Centurion, which we examined). Diego Garcia lagoon differs somewhat owing to its being almost completely surrounded by land. It has perhaps the most varied fauna in the group, and alone gives definite evidence of enlarging in every direction. Everywhere the land is entirely of coral origin. Diego Garcia shows signs of a recent elevation of a few feet, the present single island having been formed by the joining up of a series of separate islets on an elongated reef. The kuli or barachois (large shallow lakes) of the same island owe their origin to the same elevation, though elsewhere in the group they are generally due to

the successive washing up of beaches from the sea, enclosing areas of the reef. On the whole, there is singularly little change since the survey in 1837, and my impression is that Chagos has been for a long time an area of rest, and that the *present* condition of its reefs is mainly due to agencies still in action.

We have now examined the marine fauna in Salomon, Peros Banhos, Diego Garcia, and Egmont, and I would again lay stress on its comparative paucity and lack of variety as compared with the Maldives, Fiji, or even Funafuti, though many of the forms are very common. In short, its general character is rather that of the temperate than of the tropical zone.

The land fauna is largely dependent on the flora, and the latter, except on small isolated islets and selected positions, has been destroyed to allow of cocoanuts being planted. The shores are everywhere fringed with *Scaevola koenigii* and *Tournefortia argentea*, both covered with a climbing bean. Behind these there was originally a forest formed of immense mapon (*Pisonia capidia*) and takamaka (*Calophyllum inophyllum*), with a few cocoanuts, Barringtonia, banyans, and other smaller trees, and an undergrowth largely consisting of immense Asplenium and other

FIG. 2.—Lithothamnia on the Seaward Reef of Salomon Atoll, Chagos Archipelago

ferns and Psilctum, herbaceous dicotyledons being confined to the more open, dry, sandy, and stony parts; mangroves and Pandani are, curiously enough, not found. With the assistance of Dr. Simpson, we have collected the flora of each of the atolls, obtaining more than 600 specimens, about 140 species, of which probably only half are indigenous.

Of mammals there are only rats and mice, but there are traditions of dugong as well. Of birds the cardinal, sparrow, and mina have doubtless been introduced; noddies, frigates, and terns were breeding in enormous numbers on certain islands, though it was mid-winter; crab-plover, curlew, whimbal, and a sandpiper were common, and in the north-west monsoon buzzards, kites, and crows are said to be regular visitants. The green and shell turtles (*Chelone mydas* and *C. imbricata*) abound, the former coming on shore to deposit its eggs at night and the latter in the daytime. The only other reptiles are a marsh tortoise, perhaps introduced from Madagascar, and geckoes; there are no Amphibia. There is only one land shell, and arachnids and myriapods are scanty; the land crustacea are similar to those of the Maldives, but the coco crab (*Birgus latio*) is also abundant. Mr. Bainbrigge Fletcher has sorted the insects and finds about 110 species, most of which are probably indigenous; but the best season for the group would be in the rather hotter and damper north-west monsoon. On the whole, the land fauna and flora is much what one would expect to get, regarding the Chagos as a group of purely oceanic islands.

We expect to leave Mauritius toward the end of August for Cargados, Agalegas, and the submerged banks towards the Seychelles. Our cruise will be largely a dredging one, but the examination of Agalegas should be interesting. Meanwhile, Cooper and I hope to see some of the reefs round Mauritius.

J. STANLEY GARDINER.

IRON AND STEEL INSTITUTE.

FOR the first time the autumn meeting of the Iron and Steel Institute was this year held in Sheffield. An elaborate programme of visits to works and social functions was arranged, and no less than 1500 members and ladies were present, including members from all parts of the world. The opening meeting was held at the new university on September 26 under the presidency of Mr. R. A. Hadfield. Addresses of welcome were delivered by the Lord Mayor, the Master Cutler, the Vice-Chancellor of the University, Colonel Hughes (chairman of the reception committee), and by the president of the Sheffield Trades and Labour Council on behalf of the working men. Mr. Hadfield, in reply, thanked the reception committee for the admirable work it had done, and gave an interesting historical review of the Sheffield steel trade. Incidentally, he mentioned that the membership of the Iron and Steel Institute had now risen to 2200. After the reading of the minutes of the last meeting by the secretary, Mr. Bennett H. Brough, and the transaction of other routine business, the papers submitted were read and discussed. In the first paper taken Prof. J. O. Arnold described the department of iron and steel metallurgy at the University of Sheffield. The main object borne in mind in designing the laboratory was the erection on a manufacturing scale of plant producing steel by the crucible, Bessemer, and Siemens processes.

Prof. J. O. Arnold and Mr. A. McWilliam next contributed an important paper on the thermal transformations of carbon steels. For the research three steels were selected, saturated with 0.89 per cent. of carbon, unsaturated with 0.21 per cent. of carbon, and supersaturated with 1·78 per cent. of carbon. In the case of the unsaturated steel, the authors find that above Ar 3 (810° C.) the ferrite and hardenite are in mutual solution as a homogeneous mass. The Ar 3 change is accompanied by a segregation of the two constituents, which, if the cooling be slow, is probably completed in the Beta range of temperature. After a fairly rapid cooling from 950° C. the 0·21 per cent. carbon steel when quenched at 730° C. micrographically registered a segregation of ferrite so far advanced as strongly to suggest that such segregation must have begun at Ar 3 and not at Ar 2. In other words, hardenite is insoluble in ferrite in both the Beta and Alpha ranges of temperature. It however still retains its identity as hardenite whilst falling through, say, 30° C. or 40° C. of temperature in the Alpha range, namely, from the end of Ar 2 at about 720° C. to the beginning of Ar 1 at about 680° C., at which latter temperature it begins to decompose into pearlite. The heating transformations of this steel are substantially as follows:—At Ac 1 (about 710° C.) in the Alpha range the pearlite begins to change into hardenite, hence the carbide is soluble in the

Alpha range. The change to hardenite is somewhat advanced when Ac 1 merges into Ac 2 at about 720° C. owing to these points always overlapping in the heating curve. The hardenite areas probably remain unchanged on the sites previously occupied by the pearlite until the Gamma range Ac 3 is reached (at about 810° C.), when the hardenite and ferrite dissolve into each other, forming a homogeneous molecular mixture. In a saturated steel there is, on heating, a single absorption of heat at the change point Ac 1, 2, 3, the amplitude of which ranges from about 710° C. to 730° C. This change marks the transformation of the whole mass from pearlite into hardenite. On cooling, there is a very considerable evolution of heat at the single point Ar 1, 2, 3, the amplitude of which ranges from about 690° C. to 660° C. This recalescence marks the transformation of hardenite into pearlite. The particular phase of pearlite obtained depends upon the rate of cooling from 660° C. to atmospheric temperature. The emulsified phase is produced by very rapid cooling, normal pearlite by ordinary cooling, and laminated pearlite by very slow cooling. Pearlite, in which the carbide is emulsified or "sorbitic," may also be produced by tempering hardenite. The micrographic and thermal transformations of a supersaturated steel are as follows:—At Ac 1, 2, 3 the sectional ground mass of pearlite changes to hardenite, the cementite slowly segregates into larger masses until a temperature of about 900° C. is reached, then the cementite and hardenite dissolve one into the other, and a homogeneous mass of hardenite and cementite is obtained. On cooling, at about 900° C. the cementite falls out with a faint evolution of heat, and is completely segregated long before the point Ar 1, 2, 3 is reached, hence the micrographic transformations of cementite and hardenite are quite unconnected with the three thermal critical points or any of them, and are due entirely to the influence of temperature.

Mr. A. W. Richards and Mr. J. E. Stead, F.R.S., read a paper on overheated steel, describing experiments supplementing their previous work on the subject, and showing that re-heating overheated good steel can be relied upon to restore good properties to brittle material. Steel initially bad, brittle, and dangerous owing to irregularity in the distribution of the elements cannot, however, be made good by any kind of heat treatment.

Mr. L. Guillet (Paris) contributed a paper on the special steels used for motor-car construction in France. Steels with low percentages of carbon and nickel are used for parts which require case hardening and quenching. Steels with medium percentages of carbon and low percentages of nickel are used after quenching and re-heating for a large number of parts. Steels low in carbon and high in nickel are used for valves. Chromium steels with high carbon and low chromium are used for bearings. Silicon steels are used for springs and for gearing. Nickel chromium steels are used for numerous parts requiring resistance to shock.

Mr. Guillet also submitted an exhaustive paper on the use of vanadium in metallurgy. Vanadium improves the properties of alloys. In normal steel it increases the tensile strength and elastic limit, and in quenched steel it acts in the same way without increasing the brittleness. Vanadium is certainly the element which, together with carbon, acts with the greatest intensity in improving alloys of iron.

The paper read by Mr. B. Talbot (Middlesbrough) on segregation in steel ingots was one of great interest, as, although attention has been directed to the effects of segregation, little has been published as to means of lessening the amount of such segregation. The author's investigations, in which parallel tests have been made on ingots from the same heat with and without the addition of a small amount of aluminium, are of special value. The ingots were obtained from both acid and basic open-hearth furnaces, and were 5 feet 6 inches in height, the drillings for analysis being taken over the whole surface of the divided ingot. When no aluminium was added excessive segregation down the central line of the ingot occurred from 6 inches from the top to about half way down the ingot. Sulphur is the element that tends to segregate most, phosphorus next, then carbon, and finally manganese. With the use of aluminium, a billet of much more regular composition is obtained.

Mr. Douglas Upton (Jarrow) described an ingenious mechanical device for handling steel bars during the process of manufacture.

Mr. L. Dumas (Paris) read a lengthy paper on the reversible and irreversible transformations of nickel steel. The starting point of the investigation was Prof. John Hopkinson's well known experiment in 1889. Nickel, manganese and carbon, introduced into a steel, the author finds, determine alike the appearance of the same phenomenon, irreversible transformation, which is the more intense the higher the proportions in which they are present. They must also be in solution, a state which is often, as regards carbon, impossible of attainment without the aid of chromium. The nickel steels which have not undergone transformation, although too costly to be of industrial use, are of great interest as showing the result of adding nickel to steel. The homogeneity is increased, and the proportion of β-iron intensified.

Mr. G. B. Waterhouse (New York) submitted a paper giving the results of the investigation of a series of steels of constant nickel with varying carbon percentages. The results showed that nickel raises the tenacity without materially lowering the ductility. Annealing lowers the tenacity without greatly raising the ductility. Nickel lowers the transformation points Ar 3, 2 and Ar 1 about 20° for every 1 per cent. of nickel.

Captain H. G. Howorth, R.A., contributed a paper on the presence of greenish coloured markings in the fractured surfaces of test-pieces. The attention of the Ordnance Committee was directed to defects of this kind in test-pieces from tubes for guns, and the object of the paper was to ascertain to what extent the presence of such defects should weigh in accepting or rejecting the forgings for this purpose. The flaws appear to be due to slag, and in any forging subject to violent alternating stresses these flaws in prolongation may easily develop into cracks. Interesting contributions to the discussion were made by General O'Callaghan, president of the Ordnance Committee, and by General Sir J. Wolfe Murray, Master-general of the Ordnance.

Mr. Thomas Andrews, F.R.S., contributed a paper on the wear of steel rails on bridges. He received from a railway company the fractured portions of an acid Bessemer steel rail which had broken in main line service after eleven years and five months' service on a bridge. It had borne 148,000,000 tons of passing traffic, and had lost 0.69 lb. per yard per annum in weight. One of the chief causes of the fracture has been the defective segregated chemical composition of the rail. The percentages of combined carbon and manganese, found in the top of the rail head and in the bottom flange, were in excess of what should obtain in good rail steel. The chemical composition was an undesirable one, and such as is liable to lead to brittleness and sudden fracture in rail service. The high-power microscopic examinations confirmed the results arrived at by the chemical analyses and physical tests, and they demonstrated the non-uniformity of the physical and crystalline structure of the rail. The microscopic examinations have also shown the undesirability of employing rails having too high a percentage of combined carbon and manganese, and they have indicated that great care should be exercised in the thermal treatment of rails, from the ingot to the finished rail, in order to obtain a suitable microcrystalline structure resulting in a good durable rail.

The existence of troostite can no longer be questioned, but opinions as to its nature are divided. Dr. C. Benedicks (Upsala), in a paper on the subject, expressed the view that troostite is a pearlite with ultra-microscopically small particles of cementite. In all probability troostite is formed by a transformation *in situ* of martensite.

Prof. E. D. Campbell (Michigan University) contributed a paper on the occurrence of copper, cobalt, and nickel in American pig-irons. The percentages varied in the specimens analysed from 0.011 to 0.039 of copper, from a trace to 0.048 of cobalt, and from a trace to 0.072 of nickel. The only two irons containing any considerable amount of cobalt and nickel possess valuable properties for car-wheel castings.

ELECTRONS AND MATTER.

THE inaugural address on "Electronen en Materie," delivered by Prof. C. H. Wind upon taking the chair of mathematical physics and theoretical mechanics at the University of Utrecht on February 20 of this year, has lately been published (Leyden: A. W. Sijthoff). Beginning with a brief account of the gradual development of the conception of electrons, mainly through the works of H. A. Lorentz, and of its sudden corroboration after the discoveries made by Zeeman and Röntgen, the address goes on with an exposition of the notions of ether, electric displacement, electrons, and magnetic force in their present form, and traces the way to the idea of an electromagnetic mass of the electrons.

The measurements made by Kauffmann, though showing that these particles of matter probably do not possess any mass besides this electromagnetic one, of course do not prove that the same should be the case with all other particles of matter in our universe, as Wien had suggested. Yet they make this suggestion—the basis of what the author calls an electron theory *à outrance*—to some extent a plausible one. Several of the brilliant and fascinating views which this ultimate theory opens having been expounded by Mr. Balfour in his presidential address at the Cambridge meeting of the British Association, the present author directs attention to those concerning the structure of atoms, mechanism of radiation, and origin of chemical differences. He also enters into some more details, and, assuming for a while that an atom of hydrogen consists of a single positive and a single negative electron, calculates that in this system the two components would be separated by a distance perhaps 100,000 times greater than the diameter of the largest of them, and that there must be stored up in the atoms constituting one gram of hydrogen an amount of energy equivalent to that required by a mail steamer to cross the Atlantic ten times.

Poincaré has raised several serious objections against the theory. Some of these relate to the *temperate* electron theory only, and lose their weight as soon as the *ultimate* theory is adopted. To take an example. Poincaré does not feel satisfied with the changes of length in solid bodies owing to their motion through ether, as suggested by Lorentz and by Fitzgerald in order to explain the result of Michelson's experiments. Lorentz himself, however, has already shown that this hypothesis, though appearing rather bold at first sight, becomes plausible as soon as molecular forces and masses are supposed to be in the same way as electromagnetic ones affected by a translation through ether; and it is clear that this supposition is involved in that of all matter consisting of electrons, which therefore at once clears the way.

The second category of objections, those arising from the dependency of electromagnetic mass upon velocity and direction of motion, from so many instances of unequal action and reaction, from the violation even of the law of inertia, whenever electrons move with a higher speed than light, are, on the other hand, most serious in the light of the *ultimate* electron hypothesis, whereas the *temperate* theory has a way left open to dispose of them. The latter theory, indeed, does not deny the existence of matter apart from electrons and considers electromagnetic mass as something secondary. By assuming as constituents of ether hidden matter, obeying the classical principles just as well as ordinary or coarse matter, this theory will be able to account for every apparent deviation from the principles which by mathematical reasoning should be deducted as occurring in coarse matter.

But if by progress of experiment and theory the electron hypothesis in its *ultimate* form should continue to gain ground, if it should finally prove unavoidable to accept the view that matter consists entirely of electrons, then mass and momentum would cease to be what they are now in our ideas, quantities strictly invariable. There is no denying that this would involve a serious change of our general conception of nature. For the predilection and confidence with which science has for centuries been aiming at a description of the physical universe in terms only of matter and motion were based chiefly—though half unconsciously—on the idea of mass and momentum being invariable elements of nature, images or pictures of invariable elements of reality itself. Now this idea, so fundamental to our whole mechanical conception of nature, would shrink into an illusion in the light of the new theory. Of course, there would be a great advantage also. Whereas it seems now almost hopeless to involve electromagnetic phenomena in a description in terms only of matter and motion, the unity desired in our picture of the physical world would then be secured by putting it in terms of electrons and motion.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

WE learn from *Science* that an anonymous gift has been made to the Lebanon Valley College, Annville, Pa., of a hall of science to cost 16,000*l.*

MR. F. R. B. WATSON has been appointed assistant lecturer and demonstrator in engineering at the Merchant Venturers' Technical College, Bristol.

A REUTER message from New York states that the American General Education Board has received from Mr. John Rockefeller cheques to the amount of 2,000,000*l.*, in pursuance of his promise last June to give that amount in cash or securities for the endowment of higher education.

A PRIZE of 50*l.* out of the Gordon-Wigan fund will be awarded at the end of the Easter term, 1906, for a research in chemistry, of sufficient merit, carried out in the University of Cambridge. The research may be in any branch of chemistry. The dissertation, with the details of the research, must be sent to the professor of chemistry not later than the division of the Easter term, 1906.

THE year-book of the faculty of engineering of the University of Liverpool (1905–6) shows that the courses of study are so arranged as to afford a general scientific training for those intending to become engineers. The honours course affords opportunities for specialisation in a selected branch of the profession. The university training, which extends over three years, is preliminary to or supplementary of pupilage under an engineer or apprenticeship with an engineering firm.

IT is announced in *Science* that the University of Pennsylvania will receive 12,000*l.* from the estate of the late Prof. Maxwell Sommerville, who held a chair of archæology in the university. President Thwing, of Western Reserve University, we learn from the same source, has announced that Mr. Andrew Carnegie has given 5000*l.* towards the establishment of a fund of 20,000*l.* for the endowment of a chair of political economy at Western Reserve University, to bear the name of the late Senator Hanna.

THE *Engineering and Mining Journal* publishes the presidential address delivered by Mr. F. W. McNair before the Society for the Promotion of Engineering Education, in which he shows that the American mining schools have amply proved the necessity for their existence. From statistics of the six largest mining schools in America, he shows that the ratio of graduation to enrolment is increasing, that there is an enormous percentage increase in students enrolled, and that the mining school product is gradually taking the place of the so-called practical man. Dividing the twelve years available for comparison into three periods of four years, it is shown that the schools under consideration graduated one man to 13·6 million tons of the total mineral production during the first period, one to 10·2 millions in the second period, and one to 9·4 millions in the last period.

IN connection with the department of geography of the University of Cambridge, special public lectures will be delivered in the Michaelmas term by Sir Clements R. Markham, K.C.B., F.R.S., and Sir Archibald Geikie, F.R.S. The following courses, which are open to all students, whether members of the university or not, have also been arranged:—A general course in geography (with practical work) will be given by Mr. H. Yule Oldham; courses on the geography of Europe, on the principles of physical geography, and on the history of geographical discovery will also be given by Mr. Oldham. Dr. J. E. Marr, F.R.S., will lecture twice weekly on geomorphology; Dr. A. C. Haddon, F.R.S., will give courses on ethnology and on anthropogeography; and Mr.

A. R. Hinks will lecture on geographical surveying (with field work). The duties of the board of geographical studies, which is responsible for the general administration of the department, include the promotion of geographical study and research within the university, the provision of instruction in the several branches of geographical science, the administration of the geographical education fund, and the publication of schedules defining the range of the geographical examinations for degrees and diplomas of the university in geography.

THE development and strengthening of the relation which the work of technical institutes and evening classes bears to the practice and commercial aspects of our industries are undoubtedly necessary parts of further industrial progress. For this reason we welcome a recent circular issued by the Board of Education to the inspectors of these educational institutions. The Board recognises the existence of a great variety in the character and amount of the cooperation between employers of labour on the one hand and the managers of technical institutions and evening schools on the other, and in its circular gives a short account of a few typical examples with a view of showing inspectors and others the kind of work which can be done with advantage in this direction. It is true that the details of such cooperation must vary from place to place in accordance with the special requirements of each important industry, but unless it exists in one form or another full advantage will not be derived from our expenditure on technical education. The circular proceeds to give a helpful *résumé* of what has been done to encourage artisans in their studies by means of the payment of fees and the award of prizes, by increases of wages, by allowances of time for attendance at classes, and by providing opportunities for higher instruction. The circular may be commended to all employers of labour who desire that the workmen of this country may be put into the way of competing on equal terms with those of other countries.

ON Friday last Lord Rosebery, as Chancellor of the University of London, opened the Goldsmiths' College at New Cross, formerly the Goldsmiths' Institute. The development of Polytechnics under the London County Council led the Goldsmiths' Company to reconsider the constitution of the institute, which had been carried on by the company since 1888; and last year the buildings were presented by the company to the University of London, with an unoccupied adjoining site of four and a half acres, and an endowment of 5000*l.* a year for five years. An additional sum of 5000*l.* was given by the company to enable the university to carry on evening classes during 1904–5, in cooperation with the London County Council. Under the new scheme the institution has become the Goldsmiths' College, University of London, and its functions are chiefly those of a day training college for elementary teachers. These students will take the ordinary two years' course provided by the regulations of the Board of Education, and will not prepare for a university degree; but the evening class work in science and engineering will still lead up to university degrees. In the course of his remarks at the opening ceremony, Lord Rosebery said:—"The University of London is spreading itself over the metropolis. It is not too much to say that, though we cannot say that it will soon spread itself over the Empire, we may at least say that it will very soon appeal to every portion of the Empire. It is a young university. It deals with comparatively new branches of learning. It deals with the practical and the concrete, rather than with the ancient and the abstract. In that respect there is a marked difference between it and those ancient universities to which some of us owe a loyal and filial allegiance which cannot be obliterated by any newer loyalty or allegiance. The newer universities must be content, and wisely content, with something which is not antiquity, and is not tradition, but may be more immediately useful and practical than either antiquity or tradition. We, placed in the largest community in the world, with our hands, so to speak, on the very heart of the Empire, living among new wants and new aspirations, meeting new needs and new acquirements, ready, as I hope, to face the exigencies of to-day and to-morrow, are the university of the future, though we cannot trace our antiquity back to the hoary past."

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, June 8.—"The Synthesis of a Substance allied to Adrenalin." By H. D. **Dakin.** Communicated by Prof. E. H. Starling, F.R.S.

The paper contains an account of attempts to synthesise adrenalin—the physiologically active principle of the suprarenal gland. Adrenalin is commonly regarded as a secondary alcohol of the formula

$$C_6H_3(OH)_2.CH(OH).CH_2NHCH_3.$$

The corresponding ketone may be prepared by acting upon chloracetylcatechol with methylamine, and is a crystalline substance forming stable crystalline salts. The ketone may be reduced electrolytically, and the product may have the structure assigned to natural adrenalin. Although the synthetical base has many chemical and physiological properties in common with adrenalin, it probably is not the racemic form of the latter substance. The base forms extremely deliquescent salts which are unstable in hot solution; on addition of ammonia to aqueous solutions of the salts, the free base is precipitated in the form of a grey-white amorphous precipitate which is extraordinarily unstable in the dry state. Owing to experimental difficulties, satisfactory analytical and molecular weight determinations have not yet been made.

A close physiological relationship between the natural and synthetical bases is shown by the fact that, in the case of a rabbit, intravenous injection of less than 0·000001 gram is followed by a marked rise in arterial blood-pressure.

A base which is probably identical with the substance above described has been obtained by acting upon methylaminoacetylcatechol with aluminium and mercuric sulphate (D.R.-P. 157,300), and it is assumed to be a secondary alcohol. If this be correct, the formula for natural adrenalin will require modification, but more experimental evidence is needed before the question can be settled.

July 1.—"On the Influence of Collisions and of the Motion of Molecules in the Line of Sight, upon the Constitution of a Spectrum Line." By Lord **Rayleigh,** O.M., F.R.S.

Apart from the above and other causes of disturbance, a line in the spectrum of a radiating gas would be infinitely narrow. A good many years ago,[1] in connection with some estimates by Ebert, the author investigated the widening of a line in consequence of the motion of molecules in the line of sight, taking as a basis Maxwell's well known law respecting the distribution of velocities among colliding molecules, and he calculated the number of interference bands to be expected, upon a certain supposition as to the degree of contrast between dark and bright parts necessary for visibility. In this investigation no regard was paid to the collisions, the vibrations issuing from each molecule being supposed to be maintained with complete regularity for an indefinite time.

Although little is known with certainty respecting the genesis of radiation, it has long been thought that collisions act as another source of disturbance. The vibrations of a molecule are supposed to remain undisturbed while a free path is described, but to be liable to sudden and arbitrary alteration of phase and amplitude when another molecule is encountered. A limitation in the number of vibrations executed with regularity necessarily implies a certain indeterminateness in the frequency, that is, a dilatation of the spectrum line. In its nature this effect is independent of the Doppler effect—for example, it will be diminished relatively to the latter if the molecules are smaller; but the problem naturally arises of calculating the conjoint action of both causes upon the constitution of a spectrum line. This is the question considered by Mr. C. Godfrey in an interesting paper,[2] upon which it is the principal object of the present note to comment. The formulæ at which he arrives are somewhat complicated, and they are discussed only in the case in which the density of the gas is reduced without limit. According to the view of the

[1] *Phil. Mag.*, vol. xxvii., p. 298, 1889; "Scientific Papers," vol. iii., p. 258.

[2] "On the Application of Fourier's Double Integrals to Optical Problems," *Phil. Trans.*, A, vol. cxcv., p. 329, 1899.

present author, this should cause the influence of the collisions to disappear, so that the results should coincide with those already referred to where the collisions were disregarded from the outset. Nevertheless, the results of the two calculations differ by 10 per cent., that of Mr. Godfrey giving a *narrower* spectrum line than the other.

The difference of 10 per cent. is not of much importance in itself, but a discrepancy of this kind involves a subject in a cloud of doubt, which it is desirable, if possible, to dissipate. Mr. Godfrey himself characterises the discrepancy as paradoxical, and advances some considerations towards the elucidation of it. The present author has a strong feeling, which he thinks he expressed at the time, that the 10 per cent. correction is inadmissible, and that there should be no ambiguity or discontinuity in passing to the limit of free paths infinitely long. In connection with some other work he has recently resumed the consideration of the question, and he is disposed to think that Mr. Godfrey's calculation involves an error respecting the way in which the various free paths are averaged. A discussion of the subject is given in this paper.

PARIS.

Academy of Sciences, September 25.—M. Troost in the chair.—On the origin of the principle of virtual displacements: P. **Duhem**. Descartes proposed to found his system of statics on the proposition "It requires the same power (*puissance*) to raise a given weight a fixed height as to raise a weight K times as great to a height K times less." M. Duhem has found that this principle was first implicitly used by Jordanus de Nemore, in his *Tractatus de ponderibus*, dating from the thirteenth century, and traces its use by various writers down to the time of Descartes in 1637.—Observation of the total eclipse of the sun of August 30, made at Robertville, Algeria: M. **Salet**. The plan of work included (1) a search for the existence of a magnetic field in the neighbourhood of the sun by the observation of the deviation of the plane of polarisation of the coronal light; (2) the photographic study of the distribution of the polarised light of the corona; (3) the study of the atmospheric polarisation; (4) the spectro-polarisation of the corona; and (5) the photography of the ultra-violet spectrum of the corona. A *résumé* of the results, which were successful, is given.—On the observations of the total eclipse of the sun of August 30 made at Guelma by the commission from the Observatory of Algiers: Ch. **Trépied**. The results obtained include the confirmation of the supposed relationship between coronal structure and the state of solar activity, the photographic impression of the moon's disc on the corona apart from totality, the photographic registration of a very curious phenomenon of elliptical rings, and a negative exposed during the whole of totality permitting of the study of the greatest photographic extension of the corona during this eclipse and of contributing to the elucidation of the question of the intra-Mercurial planets.—New researches on the reproductive apparatus of the Mucorineæ: J. **Dauphin**. The formation of the mycelium has been followed with the microscope, day by day, up to the production of the reproductive organs. The effect of varying the nature of the carbohydrate present in the culture medium was studied, and observations made with raffinose, dextrin, starch, dulcite, erythrite, glycerin, ordinary alcohol, salicin, and quercite.—On the sensibility of the chlorophyll apparatus in ombrophobe and ombrophile plants: W. **Lubimenko**. The facts observed show clearly that the assimilating energy depends on the concentration of the pigment in the chlorophyll grains. The curve representing the assimilating energy may, according to the concentration of the pigment, rise to the upper limit of the natural radiation, as in ombrophobe plants, decrease before this limit, as in ombrophile plants, or may remain stationary, starting from a certain intensity, as in the yellow leaves of Taxus.—Spontaneous vegetation and the wholesomeness of drinking water: L. A. **Fabre**.

GÖTTINGEN.

Royal Society of Sciences.—The *Nachrichten* (physico-mathematical section), part iii. for 1905, contains the following memoirs communicated to the society:—

February 25.—A. **Sommerfeld**: The electron theory, iii.; on electrons with velocities equal to or greater than the velocity of light. H. **Happel**: On the equation of condition of monatomic substances.

May 20.—W. **Holtz**: How rotation can begin in a planetary nebula. W. **Holtz**: The reason for the star-shaped appearance of the stars. C. **Runge**: On the numerical solution of total differential equations.

June 3.—H. **Gerdien**: A new apparatus for the measurement of the electrical conductivity of the air. H. **Gerdien**: Measurements of the density of the vertical electrical conductive current in free air during the balloon ascent of May 11, 1905.

June 24.—Wilhelm **Blitz**: Contributions to the theory of "lakes" in dyeing.

The Business Notices, part i. for 1905, contains a report on the Samoa Observatory, a long obituary notice of Ernst Abbe by Prof. Voigt, and an appreciation of Georg Meissner by Prof. Max Verworn.

NEW SOUTH WALES.

Royal Society, August 2.—Mr. H. A. Lenehan, president, in the chair.—The refractive indices, with other data, of the oils of 118 species of Eucalyptus: H. G. **Smith**. In this paper the author records the refractive index, the specific gravity, the specific refractive energy, and the solubility in alcohol of the oil of each species. The material was distilled at the Technological Museum, Sydney, and most of it had been prepared for the work "Research on the Eucalypts and their Essential Oils," by Mr. R. T. Baker and himself. The oils of those species which have been obtained since that work was published are also included.

THURSDAY, OCTOBER 12, 1905.

TWO RECENT VOLUMES ON ARACHNIDA.

On Two Orders of Arachnida. Opiliones, especially the Suborder Cyphophthalmi, and Ricinulei, namely, the Family Cryptostemmatoidae. By Dr. H. J. Hansen and Dr. W. Sörensen. Pp. 1–182; 9 plates. (Published by aid of a subsidy from the Royal Society of London, Cambridge, 1904.) Price 15*s.* net.

Palaeozoische Arachniden. By Prof. Dr. Anton Fritsch. Pp. 1–80; 5 plates and many text figures. (Prag: Selbstverlag. in comm. bei Fr. Řivnáč, 1904.)

ARACHNOLOGISTS must unite in a vote of thanks to Drs. Hansen and Sörensen for their splendid achievement in producing their treatise on Arachnida. The volume, announced many years ago as in preparation, is based upon a wealth of material borrowed from every available source such as no other taxonomists have been able to examine. It is a monument of careful research, and in every way worthy of the high reputation of its authors. Though written in a foreign tongue, the letterpress contains no passage of doubtful meaning; and Hansen's inimitable drawings have received full justice from the lithographic skill of Wilson at Cambridge. The Royal Society was well advised in contributing to the cost of publication.

The first and most valuable part of the book deals with the Opiliones, a highly specialised order the morphology of which has baffled previous workers. By the comparative and careful study of a host of forms, the Danish authors have succeeded in explaining the complicated structure of the genital area, or at all events in offering an explanation which will probably stand unless ultimately disproved by embryology. They have accepted the opinions of Simon and Thorell as to the division of the order into three suborders, and supplied diagnoses of the families of the Palpatores. In the case of the Cyphophthalmi, the least known of the suborders, a complete monograph of all the species is given, together with some new anatomical details, including the important discovery that the so-called ocular tubercles bear, not eyes, but the orifices of Krohn's glands. Incidentally, Stecker's monster, Gibbocellum, is disposed of, and, it is safe to say, will never again figure in literature.

The second part deals with an order of peculiar interest, the Ricinulei or Podogona, which has existed unchanged from Carboniferous to modern times. Amongst the anatomical discoveries made by Hansen and Sörensen, two stand out as of the greatest interest, namely, the presence of a pair of tracheal respiratory organs in the prosoma and of the elements of nine somites in the opisthosoma. The association of this order with the Pedipalpi, Araneæ, and Palpigradi is of interest, even if the reasons for it are unconvincing; but surely greater prominence should have been given to the fact that Börner anticipated the Danish authors in this matter!

Exact and admirable, however, as the work is, it must not be regarded as above criticism; nor must all the statements be accepted with a childlike faith. Far from it. The limitations of the authors are well known and are sufficiently in evidence in this volume, more especially in the pages dealing with the Micrura. For example, Börner's view that the "labia" in Arachnida are not homologous sclerites is worth far more than the unreasoned dismissal it receives; and it is not very obvious why the first abdominal sternal plate in the Ricinulei is homologised with the pregenital rather than with the genital sternite of the Pedipalpi. Exception also must be taken to the application of the term "antenna" to the appendages of the first pair, and of "mandibles" to the basal segment of those of the second pair, in the Arachnida. The first change is defensible only on the grounds that the cheliceræ of the Arachnida are the homologues of the antennæ of insects and of the antennæ of the first pair in crustaceans. Those who adopt this terminology, however, must consistently apply the term "antenna" to the buccal gnathites of Peripatus. Again, the name "mandible" is presumably given to the basal segment of the appendages of the second pair because of its supposed homological correspondence to the "mandible" of the insects or crustaceans—an opinion not generally accepted.

Points of this kind, however, would scarcely be worth mentioning were it not for the apparent inclination on the part of the authors to forget the possibility of two or more views being held on matters about which embryology is, up to the present, silent. As a last word of praise, may we, in all sincerity, congratulate the authors on the considerate tone of their criticisms and on the general absence of that air of self-satisfied arrogance for which certain Danish publications on Arthropoda have gained an unenviable notoriety? It is to be hoped that the English supervision of the letterpress is not in any way responsible for this improvement.

Dr. Fritsch's monograph of the Palæozoic Arachnida is a volume of a quite different character. Plainly speaking, it is an anachronism reminiscent of the dark days of palæontology when that science was held to be independent of neontology, or at all events independent in the sense that an acquaintance with the structure of the living species of a group was regarded as superfluous for the correct determination and description of its fossil forms. The comparative morphology of recent Arachnida, even with well-preserved material for examination, is difficult enough. Was it likely, then, that any great measure of success would attend the efforts to interpret the elusive structural points of Carboniferous fossils of a palæontologist unguided by scientific familiarity with recent forms? But, although want of the requisite knowledge is plainly attested and shatters all confidence in the alleged observations and attempted restorations, yet without examination of the specimens themselves no one has the right to affirm positively that a statement is false or a drawing inaccurate in any given particular. However strongly

one may suspect the contrary, there *may* have been a scorpion in Carboniferous times with the appendages segmented as shown in the figure of *Isobuthus kralupensis* (p. 71); or another with an additional sternal plate between the normal second and third of the opisthosoma, as in the restoration of *Microlabis sternbergi* (p. 69). Most of the specimens are in continental museums; but it so happens that there is in the British Museum a fossil scorpion which Fritsch figures and describes in the present work as *Eobuthus rakovnicensis*. To one acquainted with recent scorpions, it is obvious that this fossil resembles them in all essential points. Yet Fritsch's restoration represents an animal differing from all known forms in characters falling so wide of one's experience that it is impossible to estimate their systematic value. If this be taken as a test case, it supplies convincing proof of the untrustworthiness of the drawings and diagnoses in the book; for it shows that the author's anatomical knowledge is too superficial to enable him to distinguish between fortuitous fractures and intersegmental joints in the fossil examples.

Haase's classification of the Carboniferous Arachnida is followed tolerably closely. To the Araneæ (spiders), however, is added the new suborder Pleuraraneæ; but its genera seem to be nothing but Anthracomarti. Promygale, for instance, differs from Anthracomartus only in the alleged presence of abdominal appendages. The evidence, however, for the existence of these seems to be of the slenderest kind. In the Opiliones figures the new genus Dinopilio, which presumably should be classified under the Araneæ, perhaps near the Arthrolycosidæ.

The volume nevertheless contains some valuable work, in addition to its usefulness as a catalogue and bibliographical record. The discovery that in the Carboniferous scorpions the lateral eyes are in advance of the medians, as in recent species, disposes of Thorell's classification of these animals into Anthracoscorpii and Neoscorpii. The author is also to be congratulated upon showing that the structure from which Cyclophthalmus took its name is a half-circle, not of ocelli, but of granules.

It is impossible not to regret the necessity for giving an unfavourable notice of a volume which has cost its author much time and trouble; but since his high reputation as a palæontologist and the style of the illustrations are likely to deceive the uninitiated into regarding this treatise as an epoch-making monograph, it would be unfair to do otherwise than utter a note of warning against putting reliance in its contents to those not in a position to judge of its merits for themselves.

R. I. POCOCK.

THE CITIZEN AND THE STATE.

The Citizen, a Study of the Individual and the Government. By Nathaniel Southgate Shaler. Pp. viii+339. (London: A. Constable and Co., Ltd.; 1905.) Price 5*s*. net.

PROF. SHALER, who is professor of geology at Harvard, has set before himself the practical and unambitious task of instructing the youth of the United States in the first principles of citizenship. In this he has succeeded; his work is interesting, suggestive, and extremely sensible. Not being written for the specialist, it is hardly to be called profound; and the theoretical considerations which are brought forward are of the simplest. But the author's sound common sense generally carries the reader with it. A favourable specimen of his mode of argument may be found in the discussion of woman's suffrage. There is no reference to the various views held by thinkers from Plato downwards; but probably Prof. Shaler's one-page argument is quite sufficient, that women, owing to their usually secluded lives, are not fitted in the same way as men to form judgments on political questions, but that, after all, if a majority of women should desire to vote, it would probably be best to give them the franchise, for the reason that it is most undesirable to have any considerable body of the people in a discontented state.

Only a few of the topics discussed in this book can be referred to here. Prof. Shaler takes the moderate view that it is more profitable to the commonwealth to engage the interest of a hundred thousand well-informed men in politics than to have a hundred able statesmen created for public affairs. He depreciates the importance of oratory for the statesman in the present condition of American society, regards a sound head for business and a faculty for clear statement as much more valuable, and contends that the most successful statesmen in America are not (as in England) gentlemen of independent means, but lawyers and business men, whose training has taught them how to enter into associations with other men, to limit themselves to practical aims, and to form the schemes necessary for their realisation.

Naturally, in a work proceeding from the United States, one looks for, and finds, the glorification of the ideals and great men of that country; the contrast drawn between Washington and Napoleon; the contention that the War of Independence broke out because the American colonists had outgrown the system of the mother country; the distinction, too, which is drawn between the soldier and the citizen spirit. Prof. Shaler sees clearly, and discusses with impartiality, some of the most pressing difficulties of American politics. Not much is said about trusts and tariffs, and the currency is dealt with briefly. But immigration, foreign possessions, and the negro question are quite adequately treated. Prof. Shaler laments, of course, that the streams of immigrants no longer come from the most healthy strata of society in Europe; and, in addition to criminals, paupers, and other defective persons, he would exclude those who are not able to read and write in the English language or their own. He gives no support to the view that the mere profession of the doctrines of Anarchism should be followed by condign punishment. He sees no necessity for any attempt to extend the possessions of the United States beyond the sea. "Lynch law" he holds in detestation, and calls upon young America, on the occasions of any outbursts, however natural, of the lawless desire for vengeance, to put itself under the orders of the sheriff

and even to fire on the riotous crowd. As for the negroes, whom the United States have always with them, he suggests only the need for training in the simpler arts and handicrafts; for a literary education, in his judgment, they are still wholly unfit.

PRACTICAL ORGANIC CHEMISTRY.

A Systematic Course of Practical Organic Chemistry. By Lionel Guy Radcliffe, with the assistance of Frank Sturdy Sinnatt. Pp. xi+264. (London: Longmans, Green and Co., 1905.) Price 4*s.* 6*d.*

THIS book is intended mainly for students of elementary organic chemistry. The students are supposed to work about five hours per week, and, consequently, experiments which take a longer time, and must be finished without interruption, are omitted.

The exercises include a variety of important reactions and involve work with many of the more common compounds and reagents in organic chemistry. There is a set of exercises on the fatty compounds, and another on benzene; these include instructions in the observation of melting point and boiling point, in the determination of specific gravity, of the equivalent of an acid, and of sugar by the use of Fehling's solution.

This course worked through, there is a higher course, including the preparation of such substances as anisol, benzyl chloride, and benzaldehyde, the determination of equivalents and molecular weights, and of carbon, hydrogen, nitrogen, &c.

More care might have been spent on the finish of the book. The punctuation has been neglected; *e.g.* "recrystallise until the m.p.'s do not change" (p. 16), and "recrystallise the hydrobenzamide, formed from hot alcohol" (p. 110). The diction is not what it ought to be. "Heated alone succinic acid *sublimates*" (p. 196). "See if the *example* obtained [of methyl orange] is sensitive to acids" (p. 96).

The instructions for experiments are fairly detailed and generally good. Certain mistakes have been made. The student is repeatedly directed, after having dried a preparation by calcium chloride, to distil it in presence of the drying agent (*e.g.* pp. 54, 176). If a dry distillate is desired, the distillation should be carried out after removing the calcium chloride. Again, in determining molecular weight by Victor Meyer's method, the volume and temperature of the expelled gas may surely be read without waiting so long as an hour (p. 120). Is a minute not long enough?

Under protest, the authors give a section on the qualitative analysis of organic mixtures, "for the sake of students who are taking certain examinations." "The authors are quite sensible of the fact that the analysis of such mixtures cannot be regarded as useful practical organic chemistry" (p. 172). Surely this is an impatient verdict. Qualitative analysis is a valuable training in so far as the student is led to bring book knowledge to bear on work in the laboratory, and is prevented from taking suspicion for proof. The teacher should require him, in every case, to produce a specimen (or a derivative) of each constituent of the mixture. With this stipulation, knowledge, resource and judgment are needed in organic qualitative analysis even more than in inorganic. How many different ways are available for the separation of organic substances from one another:—precipitation, the use of different solvents, ordinary and steam distillation, extraction by ether from acid and alkaline solution, hydrolysis, oxidation, &c.! Surely time spent in mastering these methods of analysis is not wasted. A. N. M.

OUR BOOK SHELF.

Die Entwickelung der electrischen Messungen. By Dr. O. Frölich. Pp. xii+192; 124 illustrations. (Brunswick: Vieweg and Son, 1905.) Price 6 marks.

THIS is the fifth of a series of scientific monographs published under the general heading *Die Wissenschaft.* It consists of an historical sketch of the development of physical measurements, especially of those connected with electrotechnics. It must be admitted that in this go-ahead age the technical man finds little time to make a retrospect of his subject; he is too much concerned with its developed aspect. Even in colleges and schools, as the publisher states, the historical side of the subject is too much neglected. The present volume is intended to remove this reproach.

To give an idea of the book, we will outline here the first chapter (on current measurement). In its first section it deals with the first galvanometer, starting with the work of Oersted and Schweigger on the action of a current on a magnetic needle. Then follow the fundamental laws of constant currents as developed by Ohm, Ampère, Biot-Savart, and the methods of demonstrating them. The astatic needles of Nobili and Davy and the measurements of Faraday are next described, and this section concludes with the methods devised for calibrating the early types of galvanometer.

The second section is called the mirror galvanometer. It describes the work of Gauss and Weber on absolute measurements, the first telegraph of Gauss and Weber (1833), and the Atlantic cable furnished with mirror galvanometers by Lord Kelvin (1858). The remainder of the section deals with improvements effected in the control of the moving system (damping, &c.), and describes the galvanometers of Wiedemann, Siemens, and Kelvin, and the more recent variants of du Bois and Rubens, Paschen, Hartman and Braun, d'Arsonval, Edelmann, and Siemens and Halske.

When it is mentioned that all this is included in thirty pages it will be realised that the descriptions are exceedingly brief. The general impression conveyed is that for a book of this kind to be of much use, fuller treatment is necessary. Still, it will serve to direct attention to the general trend of advance, and to indicate the names of those that share the chief honour of it. Its value would be considerably increased by a larger number of references to original sources of information. These are given sometimes only.

Zoologischer Jahresbericht für 1904. Edited by Prof. P. Mayer. (Berlin: Friedländer and Son, 1905.)

THE zoological station at Naples, for which this bulky volume, like its predecessors, is published, is to be congratulated on the early date of its issue and the thoroughness with which the various contributors

have done their work. In issuing a register of zoological work for 1904 so early as September of the present year, the editor and publisher have indeed beaten our own "Zoological Record"; but it must be remembered that in the present volume is included a considerable amount of literature belonging to earlier years, while it is difficult to believe that the whole of the papers for 1904 can be included.

It might be imagined, for those not conversant with the two works, that the "Zoologischer Jahresbericht" is a serious rival to the "Zoological Record," and that the publication of the one renders that of the other superfluous. As a matter of fact, this is not the case; for, in the first place, it is highly desirable that a record of zoological literature should be published in English, and, in the second, the two publications do not cover the same ground. The "Zoological Record," for instance, is specially devoted to the systematic aspect of the subject, particular pains being taken to include the names of all new species and subspecies. In the Continental work, on the other hand, systematic work is rigorously excluded, and attention concentrated on the bionomical, anatomical, and physiological aspects of the subject. The two records are therefore to a considerable extent supplemental and complementary to one another, more especially as in the one before us a somewhat full *précis* of the main subjects of the more important papers forms an important feature. The practice of including all the papers on Vertebrata under a single heading does not, indeed, appeal to us; but then, it is true, this is in some degree compensated by dividing the summary of their contents into their respective class-positions. So far as we have been able to judge, the quotations of the titles of the papers and the references to their places of publication are singularly free from error, and the volume, like its predecessors, cannot fail to be of the highest value to all workers in morphological and anatomical zoology.

R. L.

Examples in Arithmetic. By C. O. Tuckey. Pp. xii+241+xxxix. (London: George Bell and Sons, 1905.) Price 3*s*.

The Primary Arithmetic. Parts i. and ii. Edited by Dr. Wm. Briggs. Pp. 80 and 94. (London: The University Tutorial Press.) Price 6*d*. each.

THESE books are intended for the use of teachers who instruct their classes orally in the processes and rules of arithmetic, and who only require the assistance of graduated sets of exercises. In the work by Mr. Tuckey the course is fairly complete, embracing the usual commercial arithmetic, with a chapter on the application of proportion to problems in geometry and physics, and a section devoted to numerical computations by the aid of compound interest, logarithmic and trigonometrical tables, in which a little elementary trigonometry is introduced. There are examples on graphs and squared paper work, and the users of the book will have an abundant choice of exercises of modern type.

"The Primary Arithmetic" will be complete in three parts. The first part gives sets of exercises on the four simple rules and on the compound rules for money. The examples increase in difficulty by almost imperceptible stages, beginning with those of the simplest kind, and they are suitable for very young scholars. Part ii. completes the compound rules for weights and measures, including the metric system. Then follow exercises on vulgar fractions and on practice and invoices. In these two parts, as well as in the book by Mr. Tuckey, the answers to the exercises occupy a considerable space at the end of each volume.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

A Magnetic Survey of Japan.

IN NATURE of April 20 (vol. lxxi. p. 578), Prof. A. Schuster has given a comprehensive review of the magnetic survey of Japan with a friendly criticism. The responsibility of its writer may be a sufficient excuse for the following remarks partly in way of reply.

Prof. Schuster directs attention to the small space given to the description of the working of the instruments. This arises from the fact that these instruments were essentially the same as the one used in the previous survey of 1887, and described in vol. ii., pp. 178–193, of the *Journal of the College of Science*, Imperial University, Tokyo, to which the reader is referred for details. A few improvements that have since been made are mentioned in the present report, pp. 7–8.

We are glad to see that the methods adopted for calculating the corrections for heights of stations and the way of disposing with the vertical current met his approval; only Prof. Schuster seems to attribute these currents to uncertainties in the observations, whereas we infer that they are as much, if not more, due to the inadequacy of the empirical formulæ, from the fact that they vanish near the middle of the several countries treated (p. 125).

Perhaps the more important point is with regard to the question of the seat of action. To avoid confusion, it might be well to remark that the word potential is used in different senses by different writers; some use it to denote a function which satisfies the Laplacian equation $\nabla^2V=0$, and others to denote the line integral of any irrotationally distributed vector, whether the solenoidal condition be satisfied or not. It is in the latter general sense that the word is used in the report.

Now Gauss's method of separating internal and external sources of action is based upon the assumption that these sources are entirely separated from each other by a free space; in other words, the Laplacian equation holds strictly over a finite portion of the space surrounding the earth surface. This is very plausible when we consider the earth as a magnetised body, as appears *a posteriori*. But when we abandon the restriction of the solenoidal distribution the method is no more applicable, and the observation of force over a spherical surface is not sufficient to settle the seat of action, although it may be expansible in harmonic form if its distribution is continuous, so that the Gaussian expansion must be taken in "Gauss's sense" (end of first paragraph, p. 140 of the report).

The possibility of the distribution of magnetism in the space surrounding the earth surface might appear quite extravagant, and may be included amongst what Gauss calls "boldenlose Phantasien," so long as we are considering the main causes of the terrestrial magnetism; but when we come to discuss the external causes and the horizontal atmospheric current the effects of which amount to only a small fraction of the observed forces, our assumption of the distribution being thoroughly solenoidal would seem subject to doubt, or at least to require observational evidence, so that "strictly speaking, the mode of distribution must remain perfectly arbitrary so long as we adhere solely to the observed elements" of magnetic forces on a spherical surface, when no further assumption than the Newtonian law of action is admitted.

It may not be unnecessary to add here that the search for the seat of action from observations of force over a surface is an inverse problem, and includes any arbitrary distribution of magnetism the resultant effect of which vanishes on that particular surface; we can put any system of magnets or electric circuits outside the surface, provided we envelop that surface with a counteracting shell or shells over which a proper distribution of magnetism is made according to Green's method of finding the density of induced electricity on a conductor, besides any

amount of closed magnetic shells and solenoids. It will thus be seen that even if we take the internal and external sources to be detached, the plain proposition given by Prof. Schuster would appear to require a modifying clause in order to be exact. A. TANAKADATE.

Physical Laboratory, Imperial University, Tokyo, August.

A Polarisation Pattern.

THE following may be of interest to some of your readers. A cylindrical mica chimney of an Auer gas-light is placed vertically on a varnished table. If we look through it at the diffused daylight from a window reflected by the table, faint coloured bands are seen running parallel to the length of the cylinder near both edges. If observed through a Nicol's prism, the band appears very beautiful. T. TERADA.

Physical Laboratory, Science College, Imperial University, Tokyo, September 8.

A Focusing Screen for Use in Photographing Ultra-violet Spectra.

THE sensitive surface upon which Stokes projected the ultra-violet rays when observing metallic lines and absorption spectra consisted of a plate of plaster of Paris moistened with a paste of uranium phosphate acidified with phosphoric acid (*Journ. Chem. Soc.*, vol. xvii., 1864). Soret used uranium glass and solutions of fluorescent substances such as æsculine in liquid cells. I have found that the most convenient and effective screen for examining spectra with a quartz spectrograph is one such as is used for the X-rays. It may be made as follows:—a photographic plate is first cleared of silver bromide by fixing and washing, and when the film is partly dry, but the gelatin still soft, it is dusted over with a powder of barium platinocyanide crystals, so as to be somewhat thickly coated with the salt. This is fixed in the dark slide of the camera. To focus a spectrum, the slide is tilted to the necessary angle, and a somewhat powerful focusing glass with a flat field is applied to the uncoated surface of the plate, when both the visible and ultra-violet spark spectra may be plainly seen by transmission, the latter by reason of the fluorescence excited. The focusing glass should be first carefully adjusted for any visible object on the other side of a plain glass plate, such as a fine hair fastened upon it, and the position of the eye-piece is then fixed. Suitable focusing glasses are those made by Dallmeyer and by Taylor, Taylor, and Hobson. When the spectrograph has been adjusted by means of the screen, the ultra-violet lines appear quite as sharp as those in the red and yellow, even the details in the group of cadmium lines between wave-lengths 2100 and 2400 are well defined, and a very fair photograph may be obtained; but for the most accurate focusing photography must be resorted to. W. N. HARTLEY.

Royal College of Science, Dublin, October 2.

The Omission of Titles of Addresses on Scientific Subjects.

THE published reports of the British Association make an omission of an equal and opposite character to that about which your correspondent complains. Perhaps these are intended to cancel out. I refer to the publication of titles only, without any text. On receiving the last report (1904, Cambridge) I analysed this matter so far as it relates to Sections A and G, in which I am most interested. In Section A there were 83 communications, 29 of which appear by title only, and of these publication elsewhere is referred to in foot-notes in 4 cases, leaving 25 to the recollection of the audiences who heard them. Section G was better. There were 25 communications, and 13 appeared by title only; but of these 9 may be traced by those who take the trouble to consult the other publications referred to in the foot-notes. A. P. TROTTER.

Westminster, October 3.

THE INTERNATIONAL CONGRESS ON TUBERCULOSIS.

THE International Congress on Tuberculosis, held in Paris on October 2–7, has undoubtedly served as a medium for a most fruitful interchange of views by those interested in the struggle against tuberculosis. The congress was held in the Grand Palais, which from its extent enabled the members to be collected under one roof. The first day was devoted to the formal opening, when the delegates were welcomed by the President of the French Republic, who also after the close of the congress gave a reception at the Palais de l'Elysée. The chief social functions, which were characterised by complete success, comprised a reception at the Hôtel de Ville by the Municipality of Paris, an "at home" by the *Figaro*, at which performances were given by well known artistes, a soirée at the Hôtel Continental given by the president of the congress, Dr. Hérard, another at the Châtelet Theatre by the *Matin*, and a visit to Vaux de Cernay on the invitation of Dr. Henry de Rothschild.

The British Government was represented by Dr. Theodore Williams and Dr. Bulstrode, the National Association for the Prevention of Consumption by Sir William Broadbent and Dr. Perkins, while the foreign Governments and all the leading medical societies and institutions had their special official representatives.

The chief feature of the congress was reserved for the closing *séance*, when Prof. v. Behring announced that he had every reason to hope he had discovered a method of treating tuberculosis which would be as efficacious as the anti-toxin treatment of diphtheria he had first proposed in 1890.

His statement, received with great enthusiasm, was to the effect that, although he had made a great step, the value of his proposed procedure must be tested on animals in other laboratories than his own, and clinically by physicians with an intimate knowledge of the varieties of pulmonary tuberculosis, before it could be said that an actual curative medium had been found.

Prof. Behring, as had been anticipated, gave no exact details as to the method of obtaining or administering his latest therapeutic discovery, but the earlier stages of his work are to be explained in a forthcoming book entitled "Modern Problems of Phthisiogenetic and Phthisiotherapeutic Physiology illuminated by History."

His experiments have led him definitely to abandon the idea of introducing living tubercle bacilli into the human body with a therapeutic object. He has discovered a substance, to which he has given the name T.C., which represents the vital principles of the tubercle bacillus of Koch. To the presence of this substance, which possesses extraordinary fermentative and catalytic properties, is due both the hypersensibility of living organisms to Koch's tuberculin and the protective reaction against tuberculosis. This T.C. impregnates and becomes an integral part of the cells of any organism with which it comes in contact, undergoing a metamorphosis into another substance to which the name T.X. has been given.

This elaboration of T.C. in the organism is a long and perilous process. Prof. v. Behring claims to have succeeded in producing this change *in vitro* by freeing the T.C. from certain substances which impair its therapeutic action. Of these he distinguishes three groups:—(1) a substance (T.V.) only soluble in pure water, and possessing a fermentative and catalytic action. To the presence of this substance are due the toxic effects of Koch's tuberculin. One gram of this in the dry state is more toxic than a litre of the old

tuberculin. (2) A globulin (T.G.L.), soluble in neutral saline solutions, and also toxic. (3) Several non-toxic substances soluble only in ether, chloroform, and the like. The residue of the tubercle bacillus after the removal of the foregoing he terms the restbacillus; this still retains the form and staining reactions of the original tubercle bacillus. The restbacillus can be converted into an amorphous substance readily taken up by the lymphatic cells of animals undergoing a metamorphosis and leading coincidently to the production of oxyphil granules in these cells and of immunity to the tubercle bacillus in the organism as a whole.

Prof. v. Behring has convinced himself that this T.C. can be elaborated *in vitro* in a fashion which will enable it to be applied efficaciously and without danger in human therapeutics, but until this has been confirmed he does not propose to publish his full results.

The scientific interest of the congress naturally divided itself into two parts, the exhibition of pathological specimens, of models, photographs, and plans of sanatoria, instruments, sterilising machinery, and the like in the museum on the ground floor of the Grand Palais, and the actual communications made to the congress. Both presented features of great importance. Among the exhibits of more especial interest were a series of specimens indicating the results of inoculation of bovine, human, and avian tubercle in different animals, lent by the Gesundheitsamt of Berlin, and a similar series shown and thoroughly demonstrated by Dr. Lydia Rabinowitsch. The latter observer had been able to show the varying grades of virulence of the tubercle bacilli from different sources, but had not been able by transference through different animals to convert bacilli with the cultural properties of bovine bacilli into those with the cultural characters of human tubercle bacilli and *vice versâ*, although this could not be seen from the naked-eye appearance of many of the specimens. Neither had she so far repeated Nocard's results of converting avian into human or human into avian bacilli, although she exhibited an example of a bird which had suffered, apparently spontaneously, from tuberculosis, in which the cultural appearances were those of human bacilli. Dr. Calmette, of the Pasteur Institute of Lille, showed an important series of specimens from goats and kids. Kids which had been fed on the milk from mothers the mammæ of which were infected with bovine tubercle presented caseation of the mesenteric glands and also pulmonary lesions, apparently spreading through the peribronchial glands and lymphatic chain, although the retropharyngeal chain of glands remained uninfected. In cases in which the mothers had been inoculated with human or avian tuberculosis or with the Timothy bacillus only the mesenteric glands were infected. Adult goats to which doses of a culture of bovine tubercle had been administered through an œsophageal tube always died rapidly of *pulmonary tuberculosis* without apparent intestinal lesions and only a few scattered points of caseation in the mesenteric glands. Nothing approaching the degree of mesenteric affection seen in kids was found. This confirms Prof. v. Behring's announcement in 1903 that pulmonary tuberculosis might result from intestinal infection without producing local lesions at the point of entry. The Alfort Veterinary College showed a series of specimens, and others were to be seen in the museum of the college, which members of the congress were invited to visit. Amongst others were examples of the comparatively rare tuberculosis of the horse, and evidences that dogs suffer severely both from pulmonary and intestinal tuberculosis. Prof. G. Petit, of Alfort, has shown that such affections are steadily on the increase, and constitute an important factor in the campaign against tuberculosis, since a household otherwise protected to the best of human ability may become infected by a pet dog, which, having acquired tuberculosis in the streets or elsewhere, subsequently lies on the bed of children and licks their faces. The tuberculosis of dogs is more often open than had been anticipated; this means that tubercle bacilli would be constantly about their mouths, and so be readily transferred. The most common organism is the human bacillus, and the dogs most affected are those from small cafés where the air is constantly full of dust and dried sputum.

In the hygienic section were full size models showing the ordinary hotel room with its heavy hangings and dust accumulation, and the same room as it should, and could at less cost, be properly furnished with easily disinfected materials. Another group showed the great superiority in light, air, and general hygiene of a prison cell over the attic rooms with skylights, often not opening, in which most servants in Paris are accustomed to sleep.

For the purpose of receiving communications the congress was divided into four sections, the first two dealing with medical and surgical pathology and therapeutics respectively, the third with the protection of infant life, and the fourth with the protection of the adult and social hygiene.

In many subjects the two former sections overlapped, especially in dealing with the nature and varieties of tuberculosis and the value of serotherapeutics. The general conclusions appeared to be that the morphological appearances of the different varieties of the tubercle bacillus and other acid-fast bacilli were very similar, but that cultural differences existed, and that there were wide variations in toxicity. Special reports were made on this subject by Profs. Arloing, Kossel, and Ravenel. These showed that the infection of man by bovine tubercle bacilli, which are the most virulent, could occur through feeding with the unsterilised milk of tuberculous cows. All mammals appeared to suffer from infection by both types of bacilli, but no other type of mammalian bacilli could be established from cultural or morphological characters. So far as was known, tubercle bacilli modified in virulence by passing through animals other than mammals could be ultimately traced to a human or bovine origin, and restored by passage through cultures and other animals to their original forms. While the general impression seemed to be that the tubercle bacillus is in reality but one species, it was admitted that no evidence of transformation of the one type into the other, in cultural characters at any rate, had so far been produced, although varying grades of virulence in each type were recognised.

In a general study of acid-fast bacilli, Drs. Besançon and Philibert distinguish between true acid-fast bacilli which remain so under all conditions of culture, growth, and passage through animals, and those which for a single generation have acquired acid-fast characters.

They found that many bacilli grown on appropriate media containing fats, of which lanoline was the best, acquire the power for some time of resisting decolorisation by acids or by acids and alcohol. Subcultures grown on similar fatty media are also acid-fast, but subcultures on ordinary media possess no such power. To distinguish between these groups it was necessary to stain for a longer period than usual, and then to expose the films to the action of acid for many hours.

When deeply stained the tubercle bacillus will resist decolorisation for twelve to eighteen hours; the

pseudo-acid-fast bacilli resist for much shorter periods.

During the discussions on serotherapy it was stated that good results had been obtained by treatment with filtered broth cultures of tubercle bacilli as employed by Prof. Denis, of Louvain, with a new variety of tuberculin extracted from tubercle bacilli by means of a 1 per cent. solution of orthophosphoric acid introduced by Dr. Beraneck, of Neuchatel, and with the anti-toxic serum invented by Dr. Marmorek. The latter observer had made a medium of leuco-toxic serum, obtained by injecting goats with leucocytes of other animals, and spleen bouillon, and inoculated this from the very edge of young cultures of tubercle bacilli. These showed a rapid growth, and the products of their growth in this medium were injected into horses in repeated small doses; when these horses had been sufficiently immunised their blood was used as a source for the serum. This serum had given its best results in cases of surgical tuberculosis, *i.e.* diseases of joints and the like, but the effects in pulmonary tuberculosis were held to be such as to justify a more extended trial being given to this method.

In the subsection on therapeutics various methods of treatment were put forward, amongst others the intravenous injection of iodoform in suspension in a mixture of ether and liquid paraffin which had been tried with some success by Dr. Dewar, of Dunblane.

Several communications were made on the respiratory changes in the subjects of pulmonary tuberculosis, the general conclusion being that they in no wise differed from those in normal or slightly febrile individuals. A series of reports was made on the early diagnosis of pulmonary tuberculosis by radiography, cytoscopy, blood counts, and other methods. Dr. Theodore Williams pointed out that the time had not yet come for supplanting the ordinary methods of auscultation and percussion, an opinion strongly agreed to by Prof. Grancher and Dr. Turban, of Davos.

In the third section abundant evidence was given of the necessity of proper care being taken of children, especially to avoid infection, great stress being laid on the danger of their occupying the same room as a subject of pulmonary tuberculosis, and the absolute necessity for a properly supervised milk supply. In a general resolution of the congress it was decided to recommend the periodical Government inspection of all dairies, and that no public institution should make use of milk that had not either come from cows which had passed the tuberculin test or had been Pasteurised or boiled.

In the fourth section Dr. Newsholme directed attention to the diminution in the death rate from pulmonary tuberculosis which had followed the replacement of domestic by institutional relief.

A discussion on the relative merits of sanatorium and dispensary treatment resulted in the conclusion that each had its place, and that the educational factor must not be forgotten, since the diminution of tuberculosis depended more on prophylaxis than on individual treatment. The advantages of the French dispensaries over the out-patient departments of most English hospitals were that since one or more of these are situated in each district of Paris and other cities, patients have not far to come, and domiciliary visits could be made to encourage the carrying out of any precautions recommended. Owing to the distance from which patients come this was at present quite impossible to organise for London hospitals. Such a system had, however, been organised in connection with the dispensary attached to the Victoria Hospital in Edinburgh, and had been productive of most excellent results. It was in matters connected with hygiene and social factors generally that the most good resulted from the London congress, and it is to be hoped still more will follow the narration of the experience gained since that time. The real hope for the community as a whole would appear to lie in the protection of the individual, and more especially of the child, if Prof. Behring's views on latency and intestinal infection hold good, from infection rather than in the treatment of those already tuberculous, since even if treatment restore the latter to some degree of working capacity, and the average sanatorium result is put at five to seven years' prolongation of active life, they but serve as foci for fresh infection.

In addition to the actual scientific papers brought forward, perhaps the greatest and best work of the congress consisted in the private interchange of views between workers of different nationalities, and in the visits to various institutions, sanatoria, and hospitals in and around Paris.

The Pasteur Institute, the veterinary college at Alfort, the Boucicaut Hospital and the sanatoria at Bligny, Angicourt, and Ormesson were among those inspected by the greatest numbers.

At the concluding *séance* it was announced that the next congress would be held in America in three years' time.

THE BRITISH ASSOCIATION IN SOUTH AFRICA.

THE association party left Maritzburg early on Saturday morning, August 26, and proceeded through the upland districts to Colenso, where a halt of special interest had been arranged. Arriving at that now historic centre with some hours of daylight to spare, a visit was paid to the site of several battles and engagements connected with the attempts to relieve Ladysmith.

The next morning, August 27, the trains slowly steamed through one of the passes leading into Ladysmith, where evidence of the severity of the struggle of a few years ago was seen on every side in groups of graves and monuments. Ladysmith was left in the evening, and Majuba and Laing's Nek, with the scenes of struggles in the late war in northern Natal, were passed in the darkness. Daylight revealed Standerton in the Transvaal at hand, and Johannesburg was reached amid exclamations of wonder at the gigantic heaps of tailings from the gold workings which were passed during the last few miles of the journey.

Of the work done in Johannesburg in connection with the sections little need be said here, but the attendances were certainly remarkably good, and the discussions revealed a high average of capacity to discuss the various problems which were presented by the papers read. Prof. Darwin's own words at the close were felt to be fully deserved when he observed, in bringing the formal work to a close, that the meeting of the association in Cape Town and Johannesburg constituted one of the most remarkable and one of the most successful of the long series held in various centres in Great Britain, Ireland, and the colonies.

The more social functions connected with the visit to Johannesburg must be described as brilliant successes. These commenced with a reception by the mayor and town council at a conversazione held at the Wanderers' Club. His Excellency the High Commissioner, Lord Selborne, was present, and graciously received many of the more distinguished of the visitors and those who had been most prominent in preparing for the visit of the association in the different South African centres.

On the following days visits were paid to various mines, both to the underground and surface workings, and to the native and Chinese compounds; and courteous guides explained the various gold extraction processes. At one of the mines some thousands of natives delighted the visitors with a Kafir dance to the accompaniment of music on native pianos and drums.

A lecture by Prof. Ayrton on "The Distribution of Power," which had involved some weeks of preparation of elaborate machinery, was greatly appreciated, though many heard with wonder of his disparagement of the Victoria Falls as possible sources of power in the future.

A garden party at Sunnyside to which an invitation was given by Lord Selborne was very largely attended. Perhaps the great event of the Johannesburg visit was the occasion of Prof. Darwin's presidential address, which consisted of a *résumé* of the main features of the Cape Town section and the delivery of the second half of his official paper.

Opportunity was taken by Lord Selborne and Mr. George Goch, the Mayor of Johannesburg, to tender official welcomes to the association, to which the president replied in one of the graceful and fitting addresses which have constituted so noteworthy a feature of the visit.

Thursday, August 31, was taken up with a visit to Pretoria as the main attraction, with the addition of visits to the Modderfontein Dynamite Factory and the Premier Diamond Mine.

At Pretoria the whole party was entertained at luncheon at some of the principal hotels, and in the afternoon Sir Arthur Lawley, Lieutenant-Governor of the Transvaal, held a reception at the museum. The president and some of the visitors stayed overnight in Pretoria, where Mr. A. E. Shipley gave a lecture on "Fly-borne Diseases." The same evening Prof. J. O. Arnold lectured in Johannesburg on "Steel as an Igneous Rock."

During the concluding day of the Johannesburg visit, the general committee meeting and the annual meeting of members were held, when Dr. Ray Lankester was elected president of the association for the ensuing year, and the officers and council were re-elected with slight changes only in the *personnel* of the latter.

As many of the papers read at the various sections had proved of deep South African interest, it was heard with pleasure that local arrangements were being made to publish the same in a separate volume subject to the consent of the authors being obtained.

From Johannesburg and Pretoria several treks of special interest to geologists and others were arranged, and among these were journeys across country to Mafeking, which necessitated omitting the visits to Bloemfontein and Kimberley, but evidently resulted in compensation of quite another kind to those who braved the inconveniences and hardships of the journey.

Prior to leaving Johannesburg Prof. Darwin announced that some of his fellow-members desired to establish a permanent link between the association and South Africa, and it had been proposed that a subscription should be raised for a medal to be given annually to a South African student in commemoration of the visit of the British Association.

The journey to Bloemfontein did not afford much opportunity of seeing the country until early morning, when several scenes of war interest were passed. The arrival in Bloemfontein on Saturday, September 2, was followed by a public welcome by the mayor and town councillors and the local Philosophical Society in the Town Hall. The function was numerously attended, and the addresses were given and received with equal cordiality. During the morning the various public buildings were visited, and in the afternoon a reception and garden party were held.

In the absence through illness of Sir H. J. Goold-Adams, the Lieutenant-Governor, his place was taken by the Acting Chief Justice, Mr. Justice Fawkes, and Mrs. Fawkes, who graciously received the visitors. The trees and bush of the grounds afforded welcome shade, and all the accessories of the occasion were such as conduced to the comfort and pleasure of all present. In the evening Mr. A. R. Hinks lectured on "The Milky Way and the Clouds of Magellan."

On September 3 a visit was paid by train to the Government Experimental Farm at Tweespruit, a halt being made *en route* at Sannah's Post with its lamentable memories. In the course of the day a trek party left for Kimberley by way of Abraham's Kraal and Paardeberg, the scene of General Cronje's capture.

On the morning of Monday, September 4, the main party left by train and proceeded by Nowal's Pont, Naauwpoort and De Aar to Kimberley, which was reached early the next morning. The programme of entertainments for the next two days was very full. Naturally the diamond mines were the centres of greatest interest, and ample provision had been made for visits underground, to the pulsator, compounds, and surface works generally. Parties were made up of numbers sufficiently limited to admit of adequate explanation of the various processes being given, an arrangement which was much approved.

On the afternoon of the first day, September 5, the mayor and mayoress, Mr. J. D. and Mrs. Tyson, held a garden party in the Public Gardens, which afforded a much coveted opportunity for introductions of citizens to visitors. In the evening Sir Wm. Crookes gave his lecture on "Diamonds" in the Town Hall. Elaborate preparations had been made for the interesting experiments by which the lecture was illustrated, and these passed off most successfully. So numerous were the applications to attend the lecture that Sir William kindly repeated it the following afternoon.

On Wednesday morning, September 6, most of the visitors were taken by special train to the Du Toit's Pan and Wesselton mines, and the compound life of the natives was more minutely examined. The open workings at Wesselton enabled a more perfect idea to be formed of the methods which obtained in the older mines at the beginning of operations. During the day Alexandersfontein and Kenilworth attracted many visitors, and in the evening Prof. J. B. Porter, of McGill University, gave a lecture entitled "The Bearing of Engineering on Mining."

At mid-day on Thursday, September 7, the special trains for Bulawayo commenced to leave, and a journey which lasted until Saturday morning, September 9, introduced the travellers to many interesting scenes, many of which were of a type entirely different from any hitherto experienced. The richly wooded districts of British Bechuanaland called for frequent use of the camera, and not a few curios were purchased from the natives.

On arrival at Bulawayo, where the accommodation was limited, many of the party had to sleep in the train, a proceeding which, however, was hardly regarded as an inconvenience.

The library, which had been turned into a reception room for the occasion, brought a numerous company together, and the post-office counter was thronged for a considerable period owing to the great demand for the new Victoria Falls stamps just issued in

different values. The revenue had no small gains from the sales, hundreds of sets being bought up and cancelled without being used.

In the course of the morning of September 9 Prof. Darwin opened the recently acquired museum, which on being entered was found to contain a local collection of great scientific interest. Many of the visitors expressed their regret that time was not available for a more minute study than was possible on this occasion. The afternoon was taken up by a visit to Government House, the site of Lobengula's kraal, where, in the absence of the Administrator, a reception was held by the Treasurer, Mr. Newton. Lobengula's tree of justice was a centre which all sought.

In the evening Mr. D. Randall MacIver gave a lecture-report on the "Rhodesian Ruins" which attracted a numerous audience, it having been whispered abroad that his conclusions ran counter to the theories of great antiquity which have hitherto generally held the field. Mr. MacIver's address was lengthy, and dealt chiefly with one class of evidence. Although the last word has not been said upon the subject, Mr. MacIver has certainly thrown new light upon it.

The Matopos and World's View, with the tomb of Cecil Rhodes and the Shangani monument, which called for two special trains to convey the visitors, seem to have surpassed all preconceptions, and the magnificence of the surrounding views and the quiet dignity of the last resting-place of Rhodes seem to have created the same feeling in the breast of nearly everyone present, a desire to contemplate the whole scene in the silence and solitude impossible on such an occasion. A brief religious service was conducted by the Rev. Mr. Bevan at the side of the tomb.

On Monday morning, September 11, five special trains left for Victoria Falls, and the journey through the teak forests seemed a fitting prelude to the solemn grandeur of the scenes to be viewed on the morrow.

Only some thirty hours were allotted to the falls visit, but such were the arrangements made by Sir Charles Metcalfe that the main features, both of the falls, the ravine below, and the river above, could be compassed by the energetic sightseer in the time.

The first business of the day was the opening of the new bridge by Prof. Darwin, after which Palm Kloof, Livingstone Island, the Rain Forest, and many other points of vantage and interest were visited. Not a few also enjoyed a moonlight visit to the falls, the moon fortunately being full. The next morning canoes were requisitioned for trips up the lovely island-dotted river, and the "hippos" were obliging enough to put in an appearance for the occasion. Soon after noon the special trains commenced the return trip to Bulawayo, the first stage on the journey home.

At Bulawayo the trip, which, save for a few special excursions, had been of a homogeneous character, was brought to an end. The party was here divided into two sections, the one preferring the voyage home by way of Cape Town, the other *viâ* Beira and the east coast. The latter route proved to possess the greater attractiveness, judging by the numbers who elected to return that way, which was not surprising when an opportunity of making the round journey in such circumstances was considered.

Of the visit as a whole it only remains to add that it has been a success beyond the most sanguine dreams of its promoters. The hospitality throughout has been generous to the extent of lavishness, the labour of the various local committees has been as wisely exercised as it has been unremittingly pursued, and the only regret seems to have been that the time allotted to each town was necessarily so short.

That the true interests of science both in the mother country and in the colonies have been advanced by this unique meeting of the association cannot be doubted, and the results will continue to be seen in many directions after many days.

THE BRITISH SCIENCE GUILD.

The inaugural meeting of the British Science Guild will be held at the Mansion House on Monday, October 30; and the Lord Mayor, who has consented to preside, will take the chair at 4.15 p.m. The guild appeals to the people of Britain within and beyond the seas, and its chief object is to bring home to all classes the necessity of making the scientific spirit a national characteristic which shall inspire progress and determine the policy in affairs of all kinds. The organisation is associated with no political party, and its membership is open to all British subjects, whether men or women.

At the inaugural meeting of the guild, on October 30, the following officers will be proposed:—

President: the Right Hon. R. B. Haldane, K.C., M.P.; vice-presidents: the Right Hon. the Lord Mayor of London, Sir Lawrence Alma-Tadema, R.A., O.M., the Right Hon. Lord Balcarres, M.P., the Right Hon. the Earl of Berkeley, Sir William Broadbent, Bart., K.C.V.O., F.R.S., Sir Walter Buller, K.C.M.G., F.R.S., Sir J. Burdon-Sanderson, Bart., F.R.S., Major-General Sir Owen Tudor Burne, G.C.I.E., K.C.S.I., Sir William Church, Bart., Sir George Sydenham Clarke, K.C.M.G., F.R.S., Sir John Colomb, K.C.M.G., M.P., the Right Hon. the Earl of Donoughmore, the Right Hon. Earl Egerton of Tatton, Sir John Eliot, K.C.I.E., F.R.S., Sir Michael Foster, K.C.B., O.M., M.P., F.R.S., the Right Hon. Sir Edward Fry, F.R.S., Sir Archibald Geikie, F.R.S., Mr. F. Du Cane Godman, F.R.S., the Right Hon. Sir John Gorst, K.C., M.P., F.R.S., the Right Hon. Lord Haliburton, G.C.B., Sir Joseph Hooker, G.C.S.I., F.R.S., the Right Hon. Viscount Knutsford, G.C.M.G., Prof. Ray Lankester, F.R.S., Dr. J. Larmor, F.R.S., the Right Hon. Lord Lister, F.R.S., Sir Charles McLaren, Bart., K.C., M.P., the Right Hon. Sir Horace Plunkett, K.C.V.O., F.R.S., Mr. E. Robertson, K.C., M.P., the Right Hon. Lord Tennyson, P.C., G.C.M.G., His Grace the Duke of Wellington, K.G., G.C.V.O.; chairman of committees: Sir Norman Lockyer, K.C.B., F.R.S.; vice-chairmen: Sir William Abney, K.C.B., F.R.S., Sir Lauder Brunton, F.R.S., the Hon. Sir John Cockburn, K.C.M.G., Sir Gilbert Parker, M.P.; trustees: the Right Hon. Lord Strathcona and Mount Royal, G.C.M.G., Sir Henry Roscoe, F.R.S.; hon. treasurer: the Right Hon. Lord Avebury, F.R.S.; hon. assist. treasurer: Lady Lockyer, 16 Penywern Road, S.W.; hon secretary: Mr. C. Cuthbertson.

A large general committee, which will include the names of the present organising committee, will also be proposed for election.

Since the first meeting, held at the rooms of the Royal Society in April, 1904, the labours of the organising committee have been directed to securing the help of representatives of all sides of the nation's activities to secure the objects of the guild, which are

(1) To bring together as members of the guild all those throughout the Empire interested in science and scientific method, in order, by joint action, to convince the people, by means of publications and meetings, of the necessity of applying the methods of science to all branches of human endeavour, and thus to further the progress and increase the welfare of the Empire.

(2) To bring before the Government the scientific aspects of all matters affecting the national welfare.

(3) To promote and extend the application of scientific principles to industrial and general purposes.

(4) To promote scientific education by encouraging the support of universities and other institutions where the bounds of science are extended, or where new applications of science are devised.

During the first stage of the existence of the guild, the public activity of the committee was limited, by reasons of policy, because at the moment of the inception of the movement the attention of the country, and especially of Parliament, was so deeply engrossed in the fiscal problem that no other question, however important, was likely to receive due attention.

The Royal Society and British Association were founded for the promotion of natural knowledge; the Society of Arts for the encouragement of arts, manufactures, and commerce. The Science Guild, though in sympathy with these objects, is not identical in aim with any existing society. The promotion of natural knowledge is outside its sphere. Its purpose is to stimulate, not so much the acquisition of scientific knowledge, as the appreciation of its value, and the advantage of employing the methods of scientific inquiry, the study of cause and effect, in affairs of every kind. Such methods are not less applicable to the problems which confront the statesman, the official, the merchant, the manufacturer, the soldier, and the schoolmaster, than to those of the chemist or the biologist; and the value of a scientific education lies in the cultivation which it gives of the power to grasp and apply the principles of investigation employed in the laboratory to the problems which modern life presents in peace or war.

Communications may be addressed to the honorary secretary of the British Science Guild, 16 Penywern Road, London, S.W.

SIR WILLIAM WHARTON, K.C.B., F.R.S.

WILLIAM JAMES LLOYD WHARTON, second son of the late Mr. Robert Wharton, County Court Judge of York, was born in London on March 2, 1843. Educated at Burney's Academy, Gosport, he entered the Royal Navy in August, 1857, on board H.M.S. *Illustrious*, then recently commissioned as a training ship for naval cadets, stationed at Portsmouth. Passing with great credit out of the *Illustrious*, he was appointed in April, 1858, midshipman of H.M.S. *Euryalus*, on board which ship H.R.H. Prince Alfred (afterwards Duke of Edinburgh) was also serving. In November, 1860, being appointed to H.M.S. *Jason*, commissioned for service on the North American and West Indian stations, he was lent to H.M.S. *St. George*, employed on fishery duties in Newfoundland during the summer of 1861. On completing his time as midshipman he passed his examination in seamanship for the rank of lieutenant on January 13, 1863. Whilst still serving in the *Jason* he was made acting lieutenant of that ship on October 26, 1864, and at the close of the year, on the *Jason* returning to England to pay off, he at last had the opportunity to pass the examinations in gunnery and navigation necessary to qualify him for the rank of lieutenant. In these he acquitted himself brilliantly, being confirmed in his rank March 15, 1865. In December of that year he was awarded the Beaufort testimonial for passing the best examination of the year in mathematics, nautical astronomy, and navigation.

In the meantime, in July, 1865, he had been appointed to H.M.S. *Gannet*, a sloop commissioned partly for the general duties of the fleet, and partly for surveying service on the North American and West Indian stations, but acting entirely under the orders of the Commander-in-Chief. In that ship he acquired his first experience in the work to which his life was afterwards devoted, receiving the commendation of the Board of Admiralty for the zeal displayed by him on the work performed in the Bay of Fundy. The *Gannet* paid off in November, 1868.

The interest of the Commander-in-Chief, Vice-Admiral Sir James Hope, having been aroused by the ability and industry shown by Lieut. Wharton whilst serving in the *Gannet*, as well as by the distinction which he had gained in passing his examinations, when the admiral hoisted his flag at Portsmouth he offered to Wharton the appointment of flag lieutenant. The hydrographer had meanwhile promised to submit his name as second lieutenant of H.M.S. surveying vessel *Newport*; Wharton consequently considered that his services were pledged to the Surveying Service, although by adhering to it he was fully aware that he would sacrifice the prospect of certain promotion at the end of three years, but this he was prepared to do. Sir James Hope, however, took another view, and speedily arranging matters with the hydrographer, Wharton was appointed as his flag lieutenant on March 1, 1869. Whilst so employed he wrote "The History of H.M.S. *Victory*," which still commands a steady sale to the public, the proceeds being devoted to the R.N. Seamen's and Marines' Orphans' Home, Portsmouth.

In November, 1870, H.M.S. *Urgent* being fitted out to convey astronomers to the neighbourhood of Gibraltar to observe the forthcoming total eclipse of the sun, Sir James Hope gratified his flag lieutenant by permitting him to accompany the expedition as first lieutenant of the ship. He was promoted to commander March 2, 1872, on Sir J. Hope striking his flag, and the following month saw him appointed to the command of H.M. surveying vessel *Shearwater*, first on the Mediterranean station and afterwards on the east coast of Africa. In the Mediterranean his work was chiefly distinguished by a valuable contribution to science in the form of an investigation of the surface and undercurrents in the Bosphorus, setting at rest the many controversies respecting the exhaustless flow of water from the Black Sea to the Sea of Marmora by proving that an undercurrent existed as strong as that on the surface, but which invariably flowed in exactly an opposite direction. His report, which was officially published, may be considered as prescribing the method for similar inquiries. Whilst at Rodriquez, in the South Indian Ocean, he took part in observing the transit of Venus in 1874. The *Shearwater* was paid off in July, 1875, and in June the following year he commissioned the *Fawn* for surveying service in the Mediterranean, Red Sea, and east coast of Africa. Starting with a staff of officers most of whom were wholly inexperienced, Commander Wharton set himself to train them after his own ideals, and succeeded in imbuing his assistants with something of his untiring energy and love of the work. Whilst exacting the utmost that each individual was capable of giving to the service, he exercised unremitting patience and forbearance, and throughout a prolonged commission of four and a half years endeared himself to all who had the happiness to serve under him. He was sympathetic and considerate towards both officers and men, and entered heartily into all schemes for their recreation when opportunity offered. This commission of the *Fawn* was perhaps one of the most successful, as it certainly was one of the happiest, ever spent by a surveying vessel in modern times. The last two years were occupied with the survey of the Sea of Marmora, an excellent piece of work for which he and his officers received an expression of their Lordships' approbation.

On January 29, 1880, Wharton was promoted to captain, and the *Fawn* paid off at Malta at the end of the year.

An interval of leisure then followed, during which Captain Wharton published "Hydrographical Surveying." He expresses himself with characteristic modesty in the preface, but it was at once universally recognised as the standard work on the subject, and has continued to be so considered to the present time, being used both in our own and in foreign navies.

In March, 1882, he commissioned H.M.S. *Sylvia* for surveying service in the River Plate and Straits of Magellan. It was already an open secret that he was destined to succeed Captain Sir Fred. Evans as Hydrographer to the Admiralty when that officer should retire. In December, 1882, he successfully observed the transit of Venus for the second time. The anxieties of two seasons in the inhospitable climate and dangerous waters of the western part of the Straits of Magellan told upon Wharton considerably, and at this time he aged much in appearance. But, full of energy as ever, the work was pushed on rapidly in spite of the hardships and difficulties that had to be encountered, with the result that the survey was completed within the allotted time, and on returning to Montevideo in March, 1884, he left the ship and proceeded to England by mail steamer to assume the duties of hydrographer, being appointed as such on August 1, 1884, at an age younger than that of any officer who had held that responsible position. This closed his career afloat.

Wharton's administration of the hydrographic department of the Admiralty continued uninterruptedly for twenty years with constantly increasing credit, and to the great advantage of our own Navy as well as to the whole maritime world. This period covered the enormous expansion that took place both in the *personnel* and *materiel* of the fleet, causing corresponding accessions to the labour of departmental work; during the same period the number of chart plates was largely increased, and the number of charts printed annually for the fleet and for sale to the public multiplied three-fold.

Gifted with an extraordinary capacity for work, he never spared himself; the sound judgment, breadth of view, and wide scientific attainments constantly brought to bear upon the infinite variety of subjects with which he was daily called upon to deal secured for him the respect and confidence of successive Boards of Admiralty. An especial characteristic was the readiness with which the mass of information he had acquired on all sorts of subjects was available on the spur of the moment. As *ex-officio* member of the Meteorological Council, he attended its meetings assiduously and rendered valuable service to the advancement of ocean meteorology.

His personal interest in the surveying service was unceasingly manifested in the voluminous semi-official correspondence he maintained with the officers in command of surveys. Scientific subjects of whatever nature bearing on hydrography always claimed his attention, and in 1886 he was elected a Fellow of the Royal Society, serving on its council from 1888 to 1889, again from 1895 to 1897, and being again elected in 1904 was a member until his death.

As Fellow of the Royal Astronomical Society, as well as of the Royal Geographical Society, as vice-president of the latter and member of numerous committees, he did work only less important than his official work at the Admiralty. His first contribution to the literature of the Royal Society was the investigation of the great waves produced by the eruptions of Krakatoa in 1882, which had been begun by the late Sir Frederick Evans and left unfinished at his death. In 1893 he edited the journal of Captain Cook during his first voyage round the world; at the meeting of the British Association at Oxford in 1894 he presided over Section E. Various contributions to Nature appeared from time to time from his pen, the investigation of the origin and formation of coral reefs being a subject of especial interest to him. He advanced a theory, based upon the results of surveys of large numbers of these reefs, that the effect of wave action was mainly accountable for the striking uniformity of depth so frequently met with over the interior of coral banks in the open ocean, showing that wave action in open oceans extended to greater depths than was hitherto considered possible.

As a member of the coral reef committee of the Royal Society, he was largely responsible for the selection of Funafuti as the atoll to be investigated by sounding and boring operations, and he was instrumental in securing the cooperation of the Admiralty in the work, which has produced such valuable results.

He was keenly interested in the project for Antarctic exploration, but more particularly in its bearing upon terrestrial magnetism, and he took a very active part as a member of the joint committee of the Royal and Royal Geographical Societies appointed to organise it.

He was placed on the retired list in 1891, in accordance with the regulation respecting non-service at sea. Promoted to Rear-Admiral on January 1, 1895, on the Queen's birthday that year he was nominated as C.B. On the occasion of the Diamond Jubilee in 1897 he was created K.C.B.

On July 31, 1904, Sir William Wharton resigned the office of hydrographer. For some years previously he had suffered much inconvenience and pain owing to an injury to his right wrist received whilst serving in the *Shearwater*; for this and other causes he determined to relinquish the appointment. In July last, after a visit to Aix-les-Bains, he accepted with some hesitation the reiterated invitation to go out to South Africa with a party of members of the British Association, and he presided over Section E at Cape Town. Unfortunately he fell ill on the return journey from the Victoria Falls, and could not return to England as he intended, with his friends, in the *Armadale Castle*. His illness, which was at first thought to be a chill, proved to be enteric fever complicated with pneumonia, and although no effort was spared to effect his recovery he died at the observatory at Cape Town on September 29, where he was the guest of his old and valued friends Sir David and Lady Gill. He was buried at the Naval Cemetery at Simon's Town on October 1 with full naval honours, H.M. the King being represented by the Commander-in-Chief of the station. He was married, in 1880, to Lucy Georgina, daughter of Mr. Edward Holland, of Dumbledon, in Gloucestershire, and by her, who survives him, he had two daughters and three sons, two of whom are now serving in H.M. Navy.

A. M. F.

GEORGE BOWDLER BUCKTON, F.R.S.

One of the most energetic and laborious, as well as one of the oldest of our British entomologists, Mr. George Bowdler Buckton, died on September 25 in his eighty-eighth year. Although he was always interested in natural history, it is somewhat remarkable that, while many men take up the study of entomology in early life and abandon it later, all his important entomological work was executed late in life, and was carried on until a very short period before his death.

Mr. Buckton was born at Hornsey on May 24, 1818. He was privately educated, being debarred from entering a public school by an accident in boyhood which crippled him for life.

Mr. Buckton dedicated his first book, "British Aphides," to Thomas Bell, "a friend of more than forty years' standing" (in 1876), whose sympathy and encouragement had given him a taste for natural history. During the earlier part of his life Mr. Buckton resided in or near London, when his attention was given more to physical than to natural science; and he served as assistant to Prof. A. W. Hofmann at the Royal College of Chemistry. From 1845 to 1865 he published several important papers on chemical subjects (a list of which will be found in the Royal Society's Catalogue of Papers) in the *Journal of the Chemical Society*, the *Proceedings of the Royal Society*, and elsewhere; and his earliest published paper on any entomological subject appears to have been "On the Application of Cyanide of Potassium to killing Insects for the Cabinet," published in the *Zoologist* for 1854, cyanide compounds having been one of his favourite studies during his chemical researches. In the following year (1855) he published a short paper on bats in the second volume of the *Proceedings of the Linnean Society*.

He was a Fellow of the Linnean Society (1845), the Chemical Society (1852), the Royal Society (1857), and the Entomological Society (1883), and was also a member of the Entomological Society of France, a corresponding member of the Royal Academy of Sciences of Philadelphia, &c. He took great interest in these societies, attending their meetings as far as he was able, and occasionally serving on their councils; he also travelled in Italy, France, and other Continental countries, as well as in the British Islands.

In 1865 Mr. Buckton published one of the last of his chemical papers, in conjunction with Prof. W. Odling, whose daughter, Mary Ann, he married in the same year. He then settled at Haslemere, Surrey, for the remainder of his life, where he had purchased the estate at Weycombe, and built himself a house after his own design, with an observatory.

From the time of his residence at Haslemere, Mr. Buckton devoted much of his time to entomology. He formed a collection of Lepidoptera, but paid more attention to the British Homoptera, being much assisted by his children, whom he brought up in the same tastes as his own. He wrote comparatively little in the entomological journals, but published a series of very important entomological monographs from 1876 to 1905, chiefly relating to the somewhat neglected order Homoptera, which will not soon be superseded. They may here be enumerated:—1876–1883, "Monograph of British Aphides" (Ray Society), 4 vols., comprising upwards of 750 pages of letterpress, 9 plain and 134 coloured plates; 1890–1891, "Monograph of British Cicadæ or Tettigidæ" (Macmillan), 2 vols., comprising 426 pages of letterpress, 7 plain and 75 coloured plates; 1895, "The Natural History of *Eristalis Tenax*, or the Drone-Fly" (Macmillan), 1 vol., pp. vii+88, with 1 coloured and 8 plain plates. This work is illustrative of the story of Samson and the Bees. 1901–1903, "A Monograph of the Membracidæ" (Lovell Reeve), 6 parts, comprising upwards of 300 pages of letterpress, and 1 plain and 60 coloured plates. Mr. Buckton's last publication was a supplementary paper to this work, comprising 10 pages of letterpress and 2 coloured plates, forming vol. xi., part ix., of the *Transactions of the Linnean Society*, second series, zoology, and dated July, 1905.

The illustrations to Mr. Buckton's works were all drawn, and the pattern plates coloured, by himself. Some of his plates were even lithographed by himself, and most, if not all, of those which were hand-coloured were coloured by himself or his daughters. The original drawings for the work on Membracidæ have been presented to the Hope Museum at Oxford.

Mr. Buckton kept his genial force and vitality to the end; "his eye was not dimmed, nor his natural force abated." His last illness was of brief duration, and the end was very calm and peaceful. His ashes, after cremation, were deposited in a grave lined with ivy leaves in Haslemere Churchyard on Saturday, September 30.

W. F. KIRBY.

NOTES.

WE regret to see the announcement that Ferdinand Baron von Richthofen, professor of geography in the University of Berlin, died on October 7 in his seventy-third year.

THE sixth annual Huxley memorial lecture of the Anthropological Institute will be delivered on Tuesday, October 31, in the rooms of the Society of Arts, by Dr. John Beddoe, F.R.S., the subject being "Colour and Race."

A JOINT meeting of the Royal Society and the Royal Astronomical Society will be held in the rooms of the Royal Society on Thursday next, October 19, at 4.30 o'clock, to receive preliminary reports on the observations of the recent solar eclipse. It is expected that reports will be presented by the Astronomer Royal, Prof. H. L. Callendar, Mr. J. Evershed, Mr. H. F. Newall, Prof. H. H. Turner, and others.

THE annual "fungus foray" of the Essex Field Club will be held at High Beach, Epping Forest, on Saturday next, October 14; referee, Mr. George Massee, of Kew Museum. Any botanists wishing to attend should communicate with the hon. secretaries of the club, Buckhurst Hill, Essex.

THE death is announced of the Rev. S. J. Johnson at his residence, Melplash Vicarage, near Bridport, on October 9. Mr. Johnson was well known in astronomical circles for his writings upon eclipses and other astronomical matters. He was a Fellow of the Royal Astronomical Society for more than thirty-three years.

SIR EDWARD H. CARBUTT, the eminent mechanical engineer, died suddenly at his residence near Guildford on October 8 at the age of sixty-eight years. He was a past-president of the Institution of Mechanical Engineers, and a vice-president of the Iron and Steel Institute. He was an active member of the board of the National Physical Laboratory, and represented the Iron and Steel Institute on the departmental committee on the Royal College of Science and Royal School of Mines. He also represented the Iron and Steel Institute on the Institution of Civil Engineers' committee to formulate a scheme of education for engineers.

THE Municipal Museum at Hull recently acquired a valuable addition to its collection of local Roman and other remains. The specimens are principally of Roman date, and include more than 2000 coins, nearly 100 fibulæ of a great variety of patterns, several dozen buckles, pins, dress fasteners, ornaments, strap ends, bosses, spindle whorls, armlets, spoons, beads, and other objects. Among the fibulæ are two of exceptional interest, as they bear the maker's name upon them (Aveissa). There is also an extensive collection of pottery, including many vases, strainers, dishes, &c., in grey ware, as well as many fine pieces of Samian ware, several of which contain the potters' marks.

At the meeting of the Institution of Civil Engineers on Tuesday, November 7, an inaugural address will be delivered by the president, Sir Alexander R. Binnie, and the council's awards will be presented. In addition to the medals and prizes given for communications discussed at the meetings of the institution in the last session, the council of the institution has made the following awards in respect of other papers dealt with in 1904–5:—a George Stephenson medal to Captain H. R. Sankey, R.E., a Watt medal to Dr. C. Chree, F.R.S.; Telford premiums to Messrs. W. E. W. Millington, C. E. Stromeyer, C. W. Hill, F. C. Lea, W. B. Cole, W. C. Popplewell, E. H. Rigby, and W. O. Leitch, jun. For students' papers the awards are:—Miller prizes to Messrs. A. B. Potts, W. M. Hayman, R. E. Bury, T. Lees, jun., T. L. Matthews, P. J. Risdon, and F. E. Tudor.

The organisation and methods of the Japanese Naval Medical Service recently formed the subject of a communication by Surgeon-General Suzuki to the Association of Military Surgeons at Detroit. Much of the success achieved in the treatment of wounds was ascribed to a regulation requiring every member of the crew of a warship before battle to bathe and dress in perfectly clean underclothing. During engagements a 1 per cent. solution of boric acid was provided to wash the eyes free from powder, smoke, and dust, and cotton-wool plugs for the ears were issued to every man. It was impracticable during action to attempt anything but the most necessary first dressing of wounds, and after action, wherever possible, the wounded were hurried to the base hospital, and only the absolutely essential operations performed on the spot.

Recent issues of the *Proceedings of the Philadelphia Academy* include two papers on polychætous annelids from the North Pacific by Mr. J. P. Moore, and notes on Hawaiian land shells of the families Achatinellidæ and Endodontidæ by Messrs. Pilsbry and Vanatta.

An addition to the useful little guides to the contents of the Horniman Museum at Forest Hill has been issued by the London County Council in the form of "Handbook to the Marine Aquaria," and offered for sale, like all its fellows, for one penny. The handbook commences with an account of the manner in which such receptacles may be made and stocked, followed by notes on some of the common animals which may be kept therein.

We have received part ii. of the ninth volume of the *Transactions of the Leicester Literary and Philosophical Society*, containing the report of the council for the past year. Several lectures, of some of which brief abstracts are published, were delivered during the period under review, and the council reports not only an increased attendance at these lectures on the part of the public, but likewise a successful session as a whole.

A small case has been placed on one of the walls in the central hall of the Natural History Museum for the purpose of showing that the habit of depositing its eggs in the nests of other birds is not confined to the common cuckoo, and that some kinds of cuckoos hatch their own eggs. Among the series is an egg of a cow-bird among a clutch of eggs of a tyrant-bird. In this case the dissimiliarity between the eggs of the two species is very marked, but in a clutch of magpies' eggs among which is an egg of the great south European cuckoo the resemblance is marvellously close.

To the October issue of *Bird Notes and News* Dr. E. A. Wilson, late naturalist on the *Discovery*, contributes an interesting note on penguins, especially with regard to the wholesale destruction of these birds in certain districts for the sake of their oil. As regards the Antarctic species, which are at present unmolested, the author is of opinion that the emperor penguin is secure from attack during the breeding-season, although at other times of the year its destruction could be encompassed, as could that of the Adélie penguin at all seasons. Articles on the protected breeding resorts of gulls and terns in Lancashire and Lincolnshire are included in this number.

The early history of that exterminated race the Morioris of the Chatham Islands forms the subject of two papers in the *Transactions of the New Zealand Institute* for 1904. The author of one of these is of opinion that there was an immigration of Polynesians into New Zealand antecedent to the arrival of the Maories, and it is suggested that the Morioris came among these earlier voyagers. Among a number of zoological papers in the same volume reference may be made to three by Prof. Benham on the earthworms of New Zealand and the Kermadecs, in the course of one of which the author requests that observers will forward specimens from all parts of that area. Attention is directed by Archdeacon Walsh to the alleged existence in New Zealand of an undescribed lizard or salamander. To the geological section Captain Hutton communicates three papers, one on the formation of the Canterbury plains, a second on certain new Tertiary shells, and a third on the Tertiary brachiopods.

"The Cambrian Fauna of China" forms the title of a paper by Mr. C. D. Walcott constituting No. 1415 of the *Proceedings of the U.S. National Museum* (vol. xxix., pp. 1–106). The existence of Cambrian fossils in China was announced in 1883 by Baron von Richthofen, while other specimens were described in 1899. Two years ago the Carnegie Institution of Washington dispatched an expedition for the purpose of obtaining a representative collection of these fossils, and the paper before us is a preliminary account of the collection then made. The fossils of this epoch in China have proved to be extraordinarily abundant, as is indicated by the circumstance that imperfect specimens are scarcely taken into account in this preliminary notice. Brachiopods and trilobites appear to be the dominant forms, and it is confidently expected by the author that important results will follow thorough and systematic exploration and collecting.

Two out of the three articles in the September issue of the *American Naturalist* are of a somewhat technical nature, and interesting to the specialist rather than the general naturalist. In the first Mr. H. Crawley discusses the complex question of the interrelations of the parasitic protozoans of the group Sporozoa, as typified by the gregarines; while in the second Mr. F. C. Baker describes the reproductive organs of the pond-snails of the genus Limnæa. In the third and more popular article Miss Worthington supplies a large amount of information with regard to the life-history of hag-fishes, or myxinoids. These fishes abound in Monterey Bay, where they are taken on the rock-cod beds at a depth of about 300 feet. They live curled around and between the rocks, and when in health always assume a coiled position. Although they will stand much rough treatment, a decided rise of temperature proves fatal. They do much damage by stripping the flesh off fish hooked on the lines. In feeding, the tooth-plate is thrust out of the mouth, with its

two halves divergent, and the flat surface pressed against the fish and the two halves brought together, thereby tearing off a piece of flesh, which is withdrawn into the mouth.

In part i. of the fifth volume of the *Proceedings of the Rhodesia Scientific Association* are contained three papers by the president, Mr. Franklin White. Two of these are descriptions of ruins; the more important paper deals with Zimbabwe on the same lines as the more detailed account in the next issue of the *Journal of the Anthropological Institute*; the illustrations are different. Mr. White's very careful survey shows that many of the data on which have been based theories as to the age and use of the ruins are untrustworthy, and it is unfortunate for him that the negative results of his really sound work have now been overshadowed by the more positive contributions of Mr. MacIver's excavations. The third paper deals with bushman cave paintings near Matopos, and is of interest as showing their occurrence in an area outside that allotted to the "painters" in Stow's recent work; the paintings are reproduced in four coloured plates. Other illustrations in this part show the Lumene and Umnukwane ruins. Few local societies do more useful work than does the Rhodesian Scientific Association, and its *Proceedings* do it great credit.

In the *Naturwissenschaftliche Wochenschrift* for August 13 will be found a *résumé* of our knowledge of carpospore formation in the red seaweeds, which formed the subject of an address by Dr. F. Tobler to the Gesellschaft naturforschender Freunde of Berlin. The article, which deals with the work of Oltmanns and his predecessors, is illustrated with a selection of their figures.

In 1879 Prof. F. C. Schubeler, of Christiania, published some conclusions which he had formed regarding the greater productiveness and quicker ripening qualities of grain sown in northerly districts or on highlands as compared with that sown further south or on lowlands. These conclusions were not without value, as they directed attention to the matter, but Prof. N. Wille questions their accuracy in the *Biologisches Centralblatt* (September 1). Data compiled by Mr. L. P. Nilssen for different Norwegian districts tend rather to show that crops take longer to ripen near the sea than further inland.

The pages of the *Indian Forester* contain a number of useful short notes and letters contributed by officers of the Indian Forest Department, in which they record their experiences and exchange opinions. In the July number Mr. W. Mayes describes a disastrous outbreak of *Trametes pini* in the forests of *Pinus excelsa* in the Simla division; he proposes to replace the diseased poles with deodar, which is believed to be immune to this fungus. A simple but effective method of holding shifting sands by planting thorn hedges is described by Mr. L. Das. The subject of fire protection in teak forests has elicited various expressions of opinion.

The report of the industrial section of the Indian Museum, Calcutta, for the year 1904–5 has been received from the acting superintendent, Mr. Hooper. Among the recent additions to the economic section, the fragrant resin or balsam furnished by *Altingia excelsa*, the dammar-resin secreted by the Melipona or mosquito bee—both products of Burma—and a white resin from Assam, yielded by *Dipterocarpus pilosus*, are of special interest, and have been examined in the laboratory. From Burma specimens have also been sent to the art ware and ethnological sections, but the latter has been augmented principally by collections from Nepal and Tibet of musical instruments, articles of warfare, and personal ornaments.

Although at first glance the disposition of the Lower Palæozoic strata of the Island of Montreal, dipping at a very gentle angle away from the Laurentian plateau, might appear to promise a constant source of artesian water, the mineral character of the rocks forbids this. They are chiefly massive limestones, and the underground water travels along fissures and not in any special water-bearing beds, so that the success or failure of a boring cannot be foretold. Such is the conclusion reached by Prof. Adams and Mr. Leroy from a study of eighty-nine wells (Geological Survey of Canada, annual report, 1904, part O). Their report includes a general account of the geology of the Montreal district, illustrated by an excellent map on the scale of four miles to the inch, so that the pamphlet will be of interest to many who have no concern with well-sinking.

We have received from Dr. P. Bergholz a copy of the observations taken at the Bremen Meteorological Observatory during 1904. The work forms one portion of the excellent series of the "German Meteorological Yearbooks," and contains hourly values and means of the principal elements, together with the daily ranges and other useful tables. It may be remembered that Dr. Bergholz translated into German Father Viñes's very valuable work on the circulation and translation of the cyclones of the West Indies, published in 1895, some two years after the lamented death of the author.

Mr. A. Linton, Director of Agriculture for British East Africa, has published the meteorological records of that protectorate for the year 1904. It is admitted that the observations are not so satisfactory as might be, owing to want of sufficient instruments and of uniformity of exposure, but steps are being taken to remedy both these defects in the near future. The report, however, contains valuable records (mostly of rainfall) at twenty-eight stations, taken at 9h. a.m., during the year 1904, together with monthly and yearly means for as long a period as available, in some cases exceeding ten years. The amount of rainfall varies considerably, according to geographical position; in some provinces the crops suffer from lack of sufficient quantity and in others from excess. The yearly average seems to vary from about 14·7 inches at Kismayu to 73·4 inches at Mumias; both stations are practically in the latitude of the equator, the former station being at 43° E. long., near the sea-level, and the latter at 34° E. long., at an altitude of about 4000 feet.

The large part which her system of secondary and higher education has taken in Germany's extraordinary industrial success forms the subject of an article by Mr. J. L. Bashford in the current number of the *Fortnightly Review*. The essay summarises arguments which have been urged on many occasions in these columns, and advocates forcibly the need for the provision of a generous supply of higher education of the right kind, if Britain is to regain her position in the world of commerce. It is satisfactory to find a growing disposition on the part of the general Press to explain the shortcomings of our national education and to demand the provision of more funds for higher education. The same number of the review contains two other articles of interest to men of science. Dr. C. W. Saleeby, under the title of "The

Problems of Heredity," reviews at length Mr. Archdall Reid's recent book on the subject, and Miss Harriet Munroe gives a picturesque account of a visit to Walpi to study the snake dance.

FROM a study of the spectra of alloys of different metals, photographed under varying conditions of electrical excitation, atmosphere, and the proportions of the components, Mr. P. G. Nutting, of the Washington Bureau of Standards, has arrived at some interesting conclusions which confirm and supplement the results obtained by Lockyer and Roberts in 1873. Mr. Nutting's researches are described in No. 2, vol. xxii., of the *Astrophysical Journal*, and the results may be summarised as follows:—The spectra of the component metals are independent of one another when the alloy is volatilised by either the arc or the spark. The relative intensities of the component spectra are unaffected by variations of the electrical conditions or by substituting hydrogen, oxygen, mercury vapour, &c., for air as the surrounding atmosphere. *Ceteris paribus*, the spectrum of the component which has the greater atomic weight will be the brighter, when inductance is used, either with the arc or with the spark. Under certain conditions—which the author enumerates—spectroscopic analysis of alloys to within an error of about 5 per cent. should be practicable. Mr. Nutting further states that, in practice, the presence of impurities in the electrodes is of little consequence, and that when alloys are used as electrodes it is useless to attempt to intensify the spectrum of either component by varying the conditions under which the arc or spark is produced.

THE American Academy of Arts and Sciences has published a pamphlet giving a brief historical account of the origin of the Rumford fund. This fund had its origin in the gift by Count Rumford—who was born at Woburn, Massachusetts—to the American Academy of Arts and Sciences of the sum of 5000 dollars, which was simultaneous with the gift of a like sum, 1000*l*., to the Royal Society. The purpose of the fund was the same in each case, the award of a suitable premium for discoveries or improvements in heat and light. The gift was accepted by the academy, but for many years no award of the premium was made, as no claimant appeared whose merit was such in its opinion as to justify this. Meanwhile, the fund had accumulated to the amount of 4000*l*., and in view of the fact that there was no possibility of expending the income in the precise manner contemplated by Count Rumford, application was made in 1831 to the Supreme Court of the Commonwealth of Massachusetts for relief, if such should be possible. The court issued a decree which modified the possible disposition of the income of the fund in such a manner as to increase its usefulness while keeping entirely within the spirit of the original gift. At the close of the last fiscal year of the academy (1904–5) the Rumford fund amounted to 11,744*l*., the income for that year having been 510*l*. A standing committee of the academy known as the Rumford committee is charged with the supervision of the trust, and considers all applications for the Rumford premium and all applications made for grants in aid of research. The Rumford committee was first constituted a standing committee in 1833. Its members were nominated annually by the president of the academy until 1863, since which time they have been chosen in the same manner as the other officers. The Rumford fund of the Royal Society has been devoted solely to the award of the premium according to the original provisions of the trust.

OUR ASTRONOMICAL COLUMN.

FURTHER ECLIPSE RESULTS BY FRENCH OBSERVERS.—In No. 13 (September 25) of the *Comptes rendus* M. Salet publishes the preliminary results obtained by his expedition at Robertville (Algeria) during the recent total solar eclipse.

M. Salet was in charge of the mission sent to this station by the Bureau des Longitudes, the chief purpose being to make researches regarding the polarisation of the coronal light.

The first point investigated was the existence of a magnetic field in the neighbourhood of the sun, the presence of such a field being evidenced by the deviation of the plane of polarisation of the coronal light. The result indicated that there is a very slight deviation, amounting to about 2°.5, which seems to show that in spite of its great mass the sun has only a small magnetic field.

A photographic study of the distribution of the polarised light of the corona showed the bands of polarisation decreasing regularly in intensity to about one and a half diameters from the solar limb. The maximum of intensity occurs at about 5′ or 6′ from the limb, and from this distance the bands extend into the inner corona, diminishing in intensity as they approach the edge of the moon. A prominence extending across two bands shows no difference of intensity, thus proving the non-polarisation of these features of the solar atmosphere.

In order to test the atmospheric polarisation, two Savart polariscopes were pointed 90° from the sun, the one towards the pole, the other towards the equator. At this distance the quantity of polarised light during totality was insufficient to observe, although at 30° or 40° from the sun the bands remained visible throughout the period of totality.

To determine the coronal, chromospheric, or atmospheric nature of the corona spectrum lines, a "nicol" was placed so that it covered half the slit of a spectroscope and entirely extinguished the radially polarised light which is *reflected* by the corona. The resulting negative showed that the continuous spectrum of the corona differed in intensity on its two edges because of the suppression of the reflected sunlight, but the light from a prominence showed no diminution in intensity after passing through the "nicol."

The coronium line, which extends to about 4′ from the sun, is seen on both edges, as are the two calcium lines, but the latter are stronger on the edge containing the prominence.

The ultra-violet region of the spectrum, between λ 338 and λ 305, was also photographed, and shows about fifteen lines of which the nature and wave-lengths have yet to be determined.

COSMICAL EVOLUTION.—Some interesting results concerning the processes of cosmical evolution are given in a mathematical discussion, by Mr. J. H. Jeans, of Cambridge University, which appears in No. 2, vol. xxii., of the *Astrophysical Journal*.

The author first directs attention to the extremely small densities usually obtained for such binary systems as that of Algol, and points out that these densities are incompatible with the assumption that such systems are composed of incompressible homogeneous fluids; but the discussions concerning the mechanics of such systems are primarily based on this assumption, and are, therefore, in Mr. Jeans's opinion, deprived of any foundation of fact.

Mr. Jeans then discusses the probable mode of evolution of stellar and planetary systems, and arrives at the conclusion that "gravitational instability" plays the principal part in the segregation of systems from the original nebula. He contends that Laplace's "rotation" theory of cosmical evolution only takes into account a secondary factor in the process, and, in support of the "gravitational instability" theory, he shows that before rotation alone could effect the birth of a satellite a nebulous mass of, say, $10^{33 \cdot 3}$ grams would have to contract until its linear dimension was about $10^{-34 \cdot 5}$ cm., *i.e.* until its density was about 10^{137}.

If the material of the original nebula could be considered as consisting of solid particles such as are assumed

in the meteoritic hypothesis, each meteorite forming a molecule of a quasi-gas, the rotational theory would become more tenable.

VISIBILITY OF FAINT STARS AT THE LOWELL OBSERVATORY.—In No. 7, vol. xiii., of *Popular Astronomy*, Mr. Lowell publishes a chart and some figures which testify eloquently to the "seeing" and the instrumental efficiency at the Lowell Observatory, Flagstaff, Arizona.

In going over a chart of faint stars published by Prof. Tucker for magnitude comparisons, Mr. Lampland found that the faintest stars on the Lick chart were perfectly visible at Flagstaff, although the aperture employed there is only 24 inches, whereas at Lick an aperture of 36 inches is available. In the region following δ Ophiuchi, one of Prof. Tucker's richest fields, 161 stars were shown on the Lick chart. Plotting the same field, independently, Mr. Lampland obtained 173 stars, the greatest increase occurring among the fainter objects. As 15 stars marked on the Lick charts were not found, it follows that 27 were actually seen at Flagstaff which were not recorded by Prof. Tucker. Mr. Lowell remarks that this result is not definitive of what may be charted at his observatory, as moonlight and the rainy season both acted as drawbacks in the present test.

THE ORBIT OF ζ TAURI.—The spectroscopic binary ζ Tauri was included in a list of such objects published by Profs. Frost and Adams in vol. xvii. of the *Astrophysical Journal*, and attention was then directed to the peculiar spectrum of this star. Because of this peculiarity, and also on account of its long period, this object has since been observed regularly at the Yerkes Observatory, and Prof. Adams has determined the orbit, the determination being based on the measurements of the line Hγ on twenty-five plates. Owing to the great breadth of this line duplicate measures were made throughout, and, with the exception of one plate, which was rejected in the discussion, they agreed reasonably well.

The following elements were obtained as a result of the research :—

$u_1 = 100° 13'$	$a \sin i = 27{,}900{,}000$ km.
$\omega = 9° 45'$	Period U = 138 days
$e = 0{\cdot}180$	$\mu = 2°{\cdot}609$
T = 1902 Jan. 19·9	

The largest residual is $-3{\cdot}1$ km., which, considering that the determination is based upon the measurements of only one line, is regarded as satisfactory. No trace of the spectrum of the second component has been found on any of the plates yet secured (*Astrophysical Journal*, September).

THE CONSTANT OF ABERRATION.—As the result of a laborious discussion of more than 15,000 observations, Prof. Doolittle has arrived at the value $20''{\cdot}54$ for the constant of aberration. In publishing this result Prof. Doolittle states that no reasonable weighting of the values will alter it more than $0''{\cdot}01$. The above value agrees very well with the statement made in 1903 by Prof. Chandler, after a very complete investigation, that the real value would be found to be $20''{\cdot}52$, or slightly higher (the *Observatory*, No. 361).

THE NATAL GOVERNMENT OBSERVATORY.—Mr. Nevill's report of the work done in the Natal Government Observatory during 1904 contains but few references to purely astronomical observations, the chief function of the observatory being distinctly meteorological.

THE OPENING OF THE MEDICAL SESSION IN LONDON.

AS is customary, the opening of the medical session has been made the occasion at several of the schools for the distribution of prizes and the delivery of interesting addresses.

At University College, Prof. Kenwood gave an address on "Preventive Medicine, Past and Present," in the course of which he directed attention to the important position occupied by medical practitioners as guardians of the public health, and emphasised the necessity for the adequate teaching of hygiene and public health in the medical schools. He then dealt with the condition of things which should obtain in a hygienic Utopia, and pointed out that while typhus fever had been practically banished and the mortality from scarlatina reduced 80 per cent. during the past thirty years, that from measles had increased. As regards the statement that the practice of hygiene and preventive medicine tends to the preservation of the physically unfit, there is doubtless both a credit and a debit side to the account, and there can be little doubt that the credit side presents a splendid balance.

At King's College the session was opened by Prof. Clifford Allbutt, F.R.S., with an address on "Medical Education." Prof. Allbutt said that in medical education London had its own problems and difficulties, but these could only be solved on principles common to education everywhere and always.

Education must always consist of two parts—the earlier a drawing forth and refining of all the faculties and such a formation of them as habits that a right reason and virtue became easy and pleasant to us; the later the adaptation of these faculties to particular callings. The methods of specific or technical educations were pretty clearly seen; their difficulty was only the difficulty of persuading the British parent of the value of any education whatever, and of the importance of providing for it money, equipment, and time.

The university should be responsible only for a certain universal character of the mind and imagination, a training which could be given in any one of many "faculties." The five years' professional course, all too brief as it was, was now much too heavily loaded. The preliminary sciences occupied so far the larger half of it that little more than a year and a half had to suffice for the study of medicine in all its divisions and subdivisions; and yet upon that formidable burden of subjects some enthusiasts were yearning to pile more and more. The reform which was needed was to teach fewer subjects and to teach them broadly and accurately. In the five years' technical course we ought to begin with the two subjects anatomy and physiology, and teach them on university methods. No subjects made a finer training for hand and mind.

At St. George's Hospital the introductory address was delivered by Mr. Brudenell Carter, who also dealt with medical education and the importance of research. He expressed the opinion that a real and thorough training in physics should form, and eventually must form, the essential groundwork of medical education. Next in importance to physics, as a preliminary subject, he would place such a study of language, it may be of one language alone, as would enable the learner to form clear ideas himself and to express those ideas in a manner clearly intelligible to others.

At Charing Cross Hospital, Sir James Crichton-Browne delivered one of his characteristic addresses. He declared that we have hordes of undergrown, underfed, blemished, diseased, debilitated men, women, and children, who are industrially and socially inefficient; that many of our public institutions are as incompetent as the valves of a damaged heart, and that our educational machinery, our economic system, our municipal administration, and our Army are all inefficient.

If they were to be efficient medical men they must improve their personal efficiency, and see to it that they were physically efficient, intellectually efficient, and morally efficient. For facilitating the attainment of these desirable ends Sir James formulated a series of precepts or principles by which they should be guided.

He dwelt on the necessity for proper exercise and recreation, for proper meals, and for a sufficiency of sleep, declaring that the medical student should have regularly nine hours' sleep in the twenty-four.

At the Middlesex Hospital, Dr. R. A. Young took for his theme "Method in Medicine," and dealt with the need for method in teaching and in study, in research and in practice.

At St. Mary's Hospital an address on "The Public and Medical Education" was given by Dr. Wilfred Harris, in which he stated his conviction that concentration of teaching in the preliminary and intermediate subjects at one or a few centres would make for efficiency, and that one State-controlled examination should take the place of the present multitude of degree and diploma-giving bodies.

Mrs. Bryant, in the course of an address on "Ideals of Study" at the London School of Medicine for Women, said that an ideal of study was most usefully conceived, not as a scheme of learning to be achieved, but rather in its psychological essence as growing out of the primitive intellectual interests of human beings. Interest in knowledge for its own sake—the theoretic interest—was to be found more or less in every healthy normal person. According to brain type, habit, association, and other circumstances, its bent towards one or another branch of knowledge varied in individuals.

It was suggested that more should be done in elementary and secondary education (1) to develop the practical interest in relation to all the every-day problems arising naturally in the environment; and (2) to train it to a high ideal of the science and skill involved in their solution. The neglect of the practical interest in the practically minded was not only loss of good material for practical efficiency; it was also the loss of opportunity for the cultivation of the scientific interest. To inquire how a thing was made led to inquiry as to its causation, and at that point the youth or child becomes athirst for science.

At the London School of Tropical Medicine, Dr. George Nuttall, F.R.S., delivered an address on "Scientific Research in Medicine," in the course of which he pointed out the great benefits to mankind which have followed such discoveries as those of the causes and prevention of yellow fever and malaria, and that the majority of such discoveries have been made by those engaged in research and in the realms of pure science, and rarely by those guided by principles of direct and immediate utility. He urged the necessity for the endowment of research, particularly in experimental medicine, and finally proceeded to review recent work in protozoology and parasitology.

At the School of Pharmacy, Pharmaceutical Society of Great Britain, Sir Boverton Redwood delivered the address on "General Study and Specialism," and at the Royal Veterinary College Mr. Hunting discussed the career of members of the veterinary profession.

DIAMONDS.[1]

FROM the earliest times the diamond has fascinated mankind. It has been a perennial puzzle—one of the "riddles of the painful earth." It is recorded in "Sprat's History of the Royal Society" (1667) that among the questions sent by order of the society to Sir Philiberto Vernatti, resident in Batavia, was one inquiring "Whether Diamonds grow again after three or four years in the same places where they have been digged out?" The answer sent back was "Never, Or at least as the memory of man can attain to."

Of late years the subject has fascinated many men of science. The development of electricity, with the introduction of the electric furnace, has facilitated research, and I am justified in saying that if the diamond problem is not actually solved, there is every probability it shortly will be solved.

South Africa, as I will show in detail, is the favourite haunt of diamonds on this planet; it ranks with Australia and California as one of the three great gold-yielding regions. But the wealth of South Africa is not limited to gold and diamonds. It is also the illimitable home of coal—"the black diamond" of the universe. The province of Natal alone contains more coal than Britain ever owned before a single bucket had been raised; and the coal beds extend into the Orange River Colony. Valuable iron ores exist also in large quantities.

The Pipes at Kimberley.

The five diamond mines are all contained in a precious circle 3½ miles in diameter. They are irregular shaped round or oval pipes, extending vertically downwards to unknown depths, retaining about the same diameter throughout. They are considered to be volcanic necks, filled from below with a heterogeneous mixture of fragments of surrounding rocks, and of older rocks such as granite, mingled and cemented with a bluish coloured hard clayey mass, in which famous blue clay the imbedded diamonds are hidden.

How the great pipes were originally formed is hard to say. They were certainly not burst through in the ordinary manner of volcanic eruption, since the surrounding and enclosing walls show no signs of igneous action, and are not shattered or broken up even when touching the "blue ground." It is pretty certain these pipes were filled from below after they were pierced, and the diamonds were formed at some previous time and mixed with a mud volcano, together with all kinds of débris eroded from the rocks through which it erupted, forming a geological "plum pudding." The direction of flow is seen in the upturned edges of some of the strata of shale in the walls, although I was unable to see any upturning in most parts of the walls of the De Beers mine at great depths.

The breccia filling the mines, usually called "blue ground," is a collection of fragments of shale, and of various eruptive rocks, boulders, and crystals of many kinds of minerals. Indeed, a more wildly heterogeneous mixture can hardly be found anywhere else on this globe. The Kimberley mines for the first 70 feet or 80 feet are filled with so-called "yellow ground," and below that with "blue ground." This superposed yellow on blue is common to all the mines. The blue is the aboriginal ground, and owes its colour chiefly to the presence of lower oxides of iron. When atmospheric influences have access to the iron it becomes peroxidised, and the ground assumes a yellow colour. The thickness of yellow earth in the mines is therefore a measure of the depth of penetration of air and moisture. The colour does not affect the yield of diamonds. The ground mass is soapy to the touch, and friable, especially after exposure to weather. Besides diamonds, more than eighty species of minerals have been recognised in the blue ground, the most common being magnetite, ilmenite, garnet, bright green ferriferous enstatite (bronzite), a hornblendic mineral closely resembling smaragdite, calc-spar, vermiculite, diallage, jeffreysite, mica, kyanite, augite, peridot, iron pyrites, wollastonite, vaalite, zircon, chrome iron, rutile, corundum, apatite, olivine, sahlite, chromite, pseudobrookite, perofskite, biotite, and quartz.

The blue ground does not show any signs of igneous action; the fragments in the breccia are not fused at the edges. The eruptive force was probably steam or water-gas, acting under great pressure but at no high temperature.

There are many such pipes in the immediate neighbourhood of Kimberley. It may be that each volcanic pipe is the vent for its own special laboratory—a laboratory buried at vastly greater depths than we have yet reached—where the temperature is comparable with that of the electric furnace, where the pressure is fiercer than in our puny laboratories and the melting point higher, where no oxygen is present, and where masses of liquid carbon have taken centuries, perhaps thousands of years, to cool to the solidifying point. The chemist arduously manufactures infinitesimal diamonds, valueless as ornamental gems; but nature, with unlimited temperature, inconceivable pressure, and gigantic material, to say nothing of measureless time and appalling energy, produces without stint the dazzling, radiant, beautiful, coveted crystals I am enabled to show you to-night.

This hypothesis of the origin of diamonds is in many ways corroborated.

The ash left after burning a diamond invariably contains iron as its chief constituent; and the most common colours of diamonds, when not perfectly pellucid, show various shades of brown and yellow, from the palest "off colour" to almost black. They are also green, blue, pink, yellow, and orange. These variations give support to the theory advanced by Moissan that the diamond has separated from molten iron—a theory of which I shall say more presently—and also explain how it happens that stones from different mines, and even from different parts of the same mine, differ from each other. Further confirmation is given by the fact that the country round Kimberley is remarkable for its ferruginous character, and iron-saturated soil is popularly regarded as one of the indications of the near presence of diamonds. Along with carbon, molten iron dissolves other bodies which possess

[1] Abridged from a lecture delivered before the British Association at Kimberley on September 5 by Sir William Crookes, F.R.S.

tinctorial powers. One batch of iron might contain an impurity colouring the stones blue, another lot would tend towards the formation of pink stones, another of green, and so on. Cobalt, nickel, chromium, and manganese, all metals present in the blue ground, would produce these colours.

An hypothesis, however, is of little value if it only elucidates half a problem. Let us see how far we can follow out the ferric hypothesis to explain the volcanic pipes. In the first place we must remember these so-called volcanic vents are admittedly not filled with the eruptive rocks, scoriaceous fragments, &c., constituting the ordinary contents of volcanic ducts.

Selections of thin sections of some of these rocks and minerals, mounted as microscopic objects and viewed by polarised light, are not only of interest to the geologist, but are objects of great beauty.

The appearance of shale and fragments of other rocks testifies that the mélange has suffered no great heat in its present condition, and that it has been erupted from great depths by the agency of water vapour or some similar gas. How is this to be explained?

You will recollect I start with the reasonable supposition that at a sufficient depth[1] there were masses of molten iron at great pressure and high temperature, holding carbon in solution, ready to crystallise out on cooling. Far back in time the cooling from above caused cracks in superjacent strata through which water[2] found its way. On reaching the incandescent iron, the water would be converted into gas, and this gas would rapidly disintegrate and erode the channels through which it passed, grooving a passage more and more vertical in the necessity to find the quickest vent to the surface. But steam in the presence of molten or even red-hot iron liberates large volumes of hydrogen gas, together with less quantities of hydrocarbons[3] of all kinds—liquid, gaseous, and solid. Erosion commenced by steam would be continued by the other gases; it would be easy for pipes, large as any found in South Africa, to be scored out in this manner.

Sir Andrew Noble has shown that when the screw stopper of his steel cylinders in which gunpowder explodes under pressure is not absolutely perfect, gas escapes with a rush so overpowering as to score a wide channel in the metal. Some of these stoppers and vents are on the table. To illustrate my argument Sir Andrew Noble has been kind enough to try a special experiment. Through a cylinder of granite is drilled a hole 0·2 inch diameter, the size of a small vent. This is made the stopper of an explosion chamber, in which a quantity of cordite is fired, the gases escaping through the granite vent. The pressure is about 1500 atmospheres, and the whole time of escape is less than half a second. Notice the erosion produced by the escaping gases and by the heat of friction; these forces have scored out a channel more than half an inch diameter and melted the granite along their course. If steel and granite are thus vulnerable at comparatively moderate gaseous pressure, it is easy to imagine the destructive upburst of hydrogen and water-gas grooving for itself a channel in the diabase and quartzite, tearing fragments from resisting rocks, covering the country with débris, and finally, at the subsidence of the great rush, filling the self-made pipe with a water-borne magma in which rocks, minerals, iron oxide, shale, petroleum, and diamonds are violently churned in a veritable witch's cauldron! As the heat abated the water vapour would gradually give place to hot water, which forced through the magma would change some of the mineral fragments into the existing forms of to-day.

Each outbreak would form a dome-shaped hill; the eroding agency of water and ice would plane these eminences until all traces of the original pipes were lost.

Actions such as I have described need not have taken place simultaneously. As there must have been many molten masses of iron with variable contents of carbon, different kinds of colouring matter, solidifying with varying degrees of rapidity, and coming in contact with water at intervals throughout long periods of geological time—so must there have been many outbursts and upheavals, giving rise to pipes containing diamonds. And these diamonds, by sparseness of distribution, crystalline character, difference of tint, purity of colour, varying hardness, brittleness, and state of tension, have the story of their origin impressed upon them, engraved by natural forces—a story which future generations of scientific men may be able to interpret with greater precision than is possible to-day.

[1] A pressure of fifteen tons on the square inch would exist not many miles beneath the surface of the earth.

[2] There are abundant signs that a considerable portion of this part of Africa was once under water, and a fresh-water shell has been found in apparently undisturbed blue ground at Kimberley.

[3] The water sunk in wells close to the Kimberley mine is sometimes impregnated with paraffin, and Sir H. Roscoe extracted a solid hydrocarbon from the "blue ground."

Genesis of the Diamond.

Speculations as to the probable origin of the diamond have been greatly forwarded by patient research, and particularly by improved means of obtaining high temperatures, an advance we owe principally to the researches of Prof. Moissan.

Until recent years carbon was considered absolutely non-volatile and infusible; but the enormous temperatures at the disposal of experimentalists—by the introduction of electricity—show that, instead of breaking rules, carbon obeys the same laws that govern other bodies. It volatilises at the ordinary pressure at a temperature of about 3600° C., and passes from the solid to the gaseous state without liquefying. It has been found that other bodies, such as arsenic, which volatilise without liquefying at the ordinary pressure, will easily liquefy if pressure is added to temperature. It naturally follows that if along with the requisite temperature sufficient pressure is applied, liquefaction of carbon will take place, when on cooling it will crystallise. But carbon at high temperatures is a most energetic chemical agent, and if it can get hold of oxygen from the atmosphere or any compound containing it, it will oxidise and fly off in the form of carbonic acid. Heat and pressure, therefore, are of no avail unless the carbon can be kept inert.

It has long been known that iron when melted dissolves carbon, and on cooling liberates it in the form of graphite. Moissan discovered that several other metals, especially silver, have similar properties; but iron is the best solvent for carbon. The quantity of carbon entering into solution increases with the temperature.

For the manufacture of—I am afraid I must say an infinitesimal—diamond, the first necessity is to select pure iron—free from sulphur, silicon, phosphorus, &c.—and to pack it in a carbon crucible with pure charcoal from sugar. The crucible is then put into the body of the electric furnace, and a powerful arc formed close above it between carbon poles, utilising a current of 700 amperes at 40 volts pressure. The iron rapidly melts and saturates itself with carbon. After a few minutes' heating to a temperature above 4000° C.—a temperature at which the iron melts like wax and volatilises in clouds—the current is stopped, and the dazzling fiery crucible is plunged beneath the surface of cold water, where it is held until it sinks below a red heat. As is well known, iron increases in volume at the moment of passing from the liquid to the solid state. The sudden cooling solidifies the outer layer of iron and holds the inner molten mass in a tight grip. The expansion of the inner liquid on solidifying produces an enormous pressure, and under the stress of this pressure the dissolved carbon separates out in transparent forms—minutely microscopic, it is true—all the same veritable diamonds, with crystalline form and appearance, colour, hardness, and action on light the same as the natural gem.

Now commences the tedious part of the process. The metallic ingot is attacked with hot nitro-hydrochloric acid until no more iron is dissolved. The bulky residue consists chiefly of graphite, together with translucent chestnut-coloured flakes of carbon, black opaque carbon of a density of from 3·0 to 3·5, and hard as diamonds—black diamonds or carbonado, in fact—and a small portion of transparent colourless diamonds showing crystalline structure. Besides these, there may be carbide of silicon and corundum, arising from impurities in the materials employed.

The residue is first heated for some hours with strong sulphuric acid at the boiling point, with the cautious addition of powdered nitre. It is then well washed, and for two days allowed to soak in strong hydrofluoric acid

in cold, then in boiling acid. After this treatment the soft graphite disappears, and most, if not all, the silicon compounds have been destroyed. Hot sulphuric acid is again applied to destroy the fluorides, and the residue, well washed, is attacked with a mixture of the strongest nitric acid and powdered potassium chlorate, kept warm—but not above 60° C., to avoid explosions. This treatment must be repeated six or eight times, when all the hard graphite will gradually be dissolved, and little else left but graphitic oxide, diamond, and the harder carbonado and boart. The residue is fused for an hour in fluorhydrate of fluoride of potassium, then boiled out in water, and again heated in sulphuric acid. The well washed grains which resist this energetic treatment are dried, carefully deposited on a slide, and examined under the microscope. Along with numerous pieces of black diamond are seen transparent colourless pieces, some amorphous, others with a crystalline appearance. Although many fragments of crystals occur, it is remarkable I have never seen a complete crystal. All appear shattered, as if on being liberated from the intense pressure under which they were formed they burst asunder. I have singular evidence of this phenomenon. A fine piece of artificial diamond, carefully mounted by me on a microscopic slide, exploded during the night and covered the slide with fragments. Moissan's crystals of artificial diamond sometimes broke a few weeks after their preparation, and some of the diamonds which cracked weeks or even months after their preparation showed fissures covered with minute cubes. This bursting paroxysm is not unknown at the Kimberley mines.

On the screen I will project photographs of artificial diamonds manufactured in the manner described. So far, these specimens are all microscopic. The largest artificial diamond is less than one millimetre across.

These laboratory diamonds burn in the air before the blowpipe to carbonic acid. In lustre, crystalline form, optical properties, density, and hardness, they are identical with the natural stone.

In several cases Moissan separated ten to fifteen microscopic diamonds from a single ingot. The larger of these are about 0·75 mm. long, the octahedra being 0·2 mm.

Boiling and Melting Point of Carbon.

On the average, the critical point of a substance is 1·5 times its absolute boiling point. Therefore the critical point of carbon should be about 5800° Ab. But the absolute critical temperature divided by the critical pressure is for all the elements so far examined never less than 2·5, this being about the value Sir James Dewar finds for hydrogen. So that, accepting this, we get the maximum critical pressure as follows, viz. 2320 atmospheres:—

$$5800^\circ \text{ Ab.}/\text{CrP} = 2{\cdot}5, \text{ or } \text{CrP} = 5800^\circ \text{ Ab.}/2{\cdot}5, \text{ or } 2320 \text{ atmospheres.}$$

Carbon and arsenic are the only two elements that have a melting point above the boiling point; and among compounds carbonic acid and fluoride of silicium are the only other bodies with similar properties. Now the melting point of arsenic is about 1·2 times its absolute boiling point. With carbonic acid and fluoride of silicium the melting points are about 1·1 times their boiling points. Applying these ratios to carbon, we find that its melting point would be about 4400°.

Therefore, assuming the following data

Boiling point	3870° Ab.
Melting point	4400°
Critical temperature	5800°.
Critical pressure	2320 Ats.

the Rankine or Van der Waals formula calculated from the boiling point and critical data would be as follows:—

$$\log. \text{ P} = 10{\cdot}11 - 39{,}120/\text{T},$$

and this gives for a temperature of 4400° Ab. a pressure of 16·6 Ats. as the melting-point pressure. Similar rough estimates obtained by means of this formula suggest that above a temperature of 5800° Ab. no amount of pressure will cause carbon vapour to assume liquid form, whilst at 4400° Ab. a pressure of above 17 atmospheres would suffice to liquefy some of it. Between these extremes the curve of vapour pressure is assumed to be logarithmic, as represented in the accompanying diagram. The constant 39120 which occurs in the logarithmic formula enables us to calculate the latent heat of evaporation. If we assume the vapour density to be normal, or the molecule in vapour as C_2, then the heat of volatilisation of 12 grms. of carbon would be 90,000 calories; or, if the vapour is a condensed molecule like C_6, then the 12 grms. would need 30,000 calories. In the latter case the evaporation of 1 grm. of carbon would require 2500 calories, whereas a substance like zinc needs only about 400 calories.

A New Formation of Diamond.

I have long speculated as to the possibility of obtaining artificially such pressures and temperatures as would fulfil the above conditions. In their researches on the gases from fired gunpowder and cordite, Sir Frederick Abel and Sir Andrew Noble obtained in closed steel cylinders pressures as great as 95 tons to the square inch, and temperatures as high as 4000° C. According to a paper recently communicated to the Royal Society, Sir Andrew Noble, exploding cordite in closed vessels, has obtained a pressure of 8000 atmospheres, or 50 tons per square inch, with a temperature reaching in all probability 5400° Ab.

Here, then, we have conditions favourable for the liquefaction of carbon, and were the time of explosion sufficient to allow the reactions to take place, we should certainly expect to get the liquid carbon to solidify in the crystalline state.[1]

By the kindness of Sir Andrew Noble, I have been enabled to work upon some of the residues obtained in closed vessels after explosions, and I have submitted them to the same treatment that the granulated iron had gone through. After weeks of patient toil I removed the amorphous carbon, the graphite, the silica,[2] and other constituents of the ash of cordite, and obtained a residue among which, under the microscope, crystalline particles could be distinguished. Some of these particles, from their crystalline appearance and double refraction, were silicon carbide; others were probably diamonds. The whole residue was dried and fused at a good red heat in an excess of potassium bifluoride, to which was added during fusion 5 per cent. of nitre. (Previous experiments had shown me that this mixture readily attacked and dissolved silicon carbide; unfortunately it also attacks diamond to a slight degree.) The residue, after thorough washing and then heating in fuming sulphuric acid, was washed, dried, and the largest crystalline particles picked out and mounted. All the operations of washing and acid treatment were performed in a large platinum crucible by decantation (except the preliminary attack with nitric acid and potassium chlorate, when a hard glass vessel was used); the final result was washed into a shallow watch-glass, and the selection made under the microscope.

I project on the screen a few photographs of these crystals. From the treatment they have undergone, chemists will agree with me that diamonds only could stand such an ordeal; on submitting them to skilled crystallographic authorities my opinion is confirmed. Speaking of the one before you (303), Prof. Bonney calls it "a diamond showing octahedral planes with dark boundaries due to high refracting index." After careful examination, Prof. Miers writes of the same crystal diamond:—"I think one may safely say that the position and angles of its faces, *and of its cleavages*, the absence of birefringence, and the high refractive index, are all compatible with the properties of the diamond crystallising in the form of an octahedron. Others of the remaining crystals, which show a similar high refractive index, appeared to me to present the same features."

[1] Sir James Dewar, in a Friday evening discourse at the Royal Institution, 1880, showed an experiment proving that the temperature of the interior of a carbon tube heated by an outside electric arc was higher than that of the oxy-hydrogen flame. He placed a few small crystals of diamond in the carbon tube, and, maintaining a current of hydrogen to prevent oxidation, raised the temperature of the tube in an electric furnace to that of the arc. In a few minutes the diamond was transformed into graphite. At first sight this would seem to show that diamond cannot be formed at temperatures above that of the arc. It is probable, however, for reasons given above, that at exceedingly high pressures the result would be different

[2] The silica was in the form of spheres, perfectly shaped and transparent, mostly colourless, but among them several of a ruby colour. When 5 per cent. of silica was added to cordite, the residue of the closed vessel explosion contained a much larger quantity of these spheres.

It would have been more conclusive had I been able to get further evidence as to the density and hardness of the crystals; but I am still working at the subject, and hope to add these confirmatory tests. From what I have already said, I think there is no doubt that in these closed vessel explosions we have another method of producing the diamond artificially.

Sensational as is the story of the diamond industry in South Africa, quite another aspect fixes the attention of the chemist. The diamonds come out of the mines, but how did they get in? How were they formed? What is their origin?

Gardner Williams, who knows more about diamonds than any man living, is little inclined to indulge in speculation. In his fascinating book[1] he frankly says:—

"I have been frequently asked, 'What is your theory of the original crystallisation of the diamond?' and the answer has always been, 'I have none; for after seventeen years of thoughtful study, coupled with practical research, I find that it is easier to "drive a coach and four" through most theories that have been propounded than to suggest one which would be based on any non-assailable data.' All that can be said is that in some unknown manner carbon, which existed deep down in the internal regions of the earth, was changed from its black and uninviting appearance to the most beautiful gem which ever saw the light of day."

Meteoric Diamonds.

Another diamond theory appeals to the fancy. It is said the diamond is a gift from Heaven, conveyed to earth in meteoric showers. The suggestion, I believe, was first broached by A. Meydenbauer,[2] who says:—"The diamond can only be of cosmic origin, having fallen as a meteorite at later periods of the earth's formation. The available localities of the diamond contain the residues of not very compact meteoric masses which may, perhaps, have fallen in prehistoric ages, and which have penetrated more or less deeply, according to the more or less resistant character of the surface where they fell. Their remains are crumbling away on exposure to the air and sun, and the rain has long ago washed away all prominent masses. The enclosed diamonds have remained scattered in the river beds, while the fine light matrix has been swept away."

According to this hypothesis, the so-called volcanic pipes are simply holes bored in the solid earth by the impact of monstrous meteors—the larger masses boring the holes, while the smaller masses, disintegrating in their fall, distributed diamonds broadcast. Bizarre as such a theory appears, I am bound to say there are many circumstances which show that the notion of the heavens raining diamonds is not impossible.

The most striking confirmation of the meteoric theory comes from Arizona. Here, on a broad open plain, over an area about five miles in diameter, have been scattered one or two thousand masses of metallic iron, the fragments varying in weight from half a ton to a fraction of an ounce. There is little doubt these masses formed part of a meteoric shower, although no record exists as to when the fall took place. Curiously enough, near the centre, where most of the meteorites have been found, is a crater with raised edges three-quarters of a mile in diameter and about 600 feet deep, bearing exactly the appearance which would be produced had a mighty mass of iron struck the ground and buried itself deep under the surface. Altogether ten tons of this iron have been collected, and specimens of the Canyon Diablo meteorite are in most collectors' cabinets.

An ardent mineralogist—the late Dr. Foote—cutting a section of this meteorite, found the tools were injured by something vastly harder than metallic iron. He examined the specimen chemically, and soon after announced to the scientific world that the Canyon Diablo meteorite contained black and transparent diamonds. This startling discovery was afterwards verified by Profs. Moissan and Friedel, and Moissan, working on 183 kilograms of the Canyon Diablo meteorite, has recently found smooth black diamonds and transparent diamonds in the form of octahedra with rounded edges, together with green hexagonal crystals of carbon silicide. The presence of carbon silicide in the meteorite shows that it must, at some time, have experienced the temperature of the electric furnace. Since this revelation, the search for diamonds in meteorites has occupied the attention of chemists all over the world.

I am enabled to show you photographs of true diamonds I myself have extracted from the Canyon Diablo meteorite. A fine slab of the meteorite, weighing about seven pounds, is on the table before you.

Here, then, we have incontestable proof of the truth of the meteoric theory. Under atmospheric influences the iron would rapidly oxidise and rust away, colouring the adjacent soil with red oxide of iron. The meteoric diamonds would be unaffected, and left on the surface of the soil, to be found haphazard when oxidation had removed the last proof of their celestial origin. That there are still lumps of iron left at Arizona is merely due to the extreme dryness of the climate and the comparatively short time that the iron has been on our planet. We are here witnesses to the course of an event which may have happened in geologic times anywhere on the earth's surface.

Although in Arizona diamonds have fallen from the skies, confounding our senses, this descent of precious stones is what may be called a freak of nature rather than a normal occurrence. To the modern student of science there is no great difference between the composition of our earth and that of extra-terrestrial masses. The mineral peridot is a constant extra-terrestrial visitor, present in most meteorites; and yet no one doubts that peridot is also a true constituent of rocks formed on this earth. The spectroscope reveals that the elementary composition of the stars and the earth is pretty much the same; and the spectroscope also shows that meteorites have as much of earth as of heaven in their composition. Indeed, not only are the self-same elements present in meteorites, but they are combined in the same way to form the same minerals as in the crust of the earth.

It is certain from observations I have made, corroborated by experience gained in the laboratory, that iron at a high temperature and under great pressure—conditions existent at great depths below the surface of the earth—acts as the long-sought solvent for carbon, and will allow it to crystallise out in the form of diamond. But it is also certain, from the evidence afforded by the Arizona and other meteorites, that similar conditions have existed among bodies in space, and that on more than one occasion a meteorite freighted with jewels has fallen as a star from the sky.

Many circumstances point to the conclusion that the diamond of the chemist and the diamond of the mine are strangely akin as to origin. It is evident that the diamond has not been formed *in situ* in the blue ground. The genesis must have taken place at vast depths under enormous pressure. The explosion of large diamonds on coming to the surface shows extreme tension. More diamonds are found in fragments and splinters than in perfect crystals; and it is noteworthy that although these splinters and fragments must be derived from the breaking up of a large crystal, yet in only one instance have pieces been found which could be fitted together, and these occurred at different levels. Does not this fact point to the conclusion that the blue ground is not their true matrix? Nature does not make fragments of crystals. As the edges of the crystals are still sharp and unabraded, the *locus* of formation cannot have been very distant from the present sites. There were probably many sites of crystallisation differing in place and time, or we should not see such distinctive characters in the gems from different mines, nor, indeed, in the diamonds from different parts of the same mine.

It is not difficult to imagine that masses of iron saturated with carbon existed formerly at a sufficient depth below the present mines, where temperature and pressure would produce the reactions which laboratory experiments show to be probable.

Many crystals of diamonds have their surfaces beautifully marked with equilateral triangles, interlaced and of varying sizes. Under the microscope these markings appear as shallow depressions sharply cut out of the surrounding surface; these depressions were supposed by Gustav Rose to indicate the probability that the diamonds at some

[1] "The Diamond Mines of South Africa," p. 510. (Macmillans, 1902.)
[2] *Chemical News*, vol. lxi., p. 209, 1890.

previous time had been exposed to incipient combustion. Rose also noted that striations appeared on the surfaces of diamonds burnt before the blowpipe.

I have tried many times to imitate these markings by partial combustion of clear crystals of diamond, but have not succeeded in reproducing triangles of such beauty as you see formed by nature. According to the crystalline face exposed to incipient combustion the etchings are triangular or cubical, and sometimes intermediate between the two. I throw on the screen magnified photographs of these etchings, and you will observe that while the triangular or box-like tendency is very apparent, there is an absence of regularity and sharpness.

The artificial markings are closer massed, looking as if the diamond during combustion had been dissected into triangular and rectangular flakes, while the markings natural to crystals appear as if produced by the crystallising force as they were being built up.

Certain artificial diamonds present the appearance of an elongated drop. I have seen diamonds which have exactly the appearance of drops of liquid separated in a pasty condition and crystallised on cooling. Diamonds are sometimes found with little appearance of crystallisation, but with rounded forms similar to those which a liquid might assume if kept in the midst of another liquid with which it would not mix. Other drops of liquid carbon retained for sufficient time above their melting point would coalesce with adjacent drops, and on slow cooling would separate in the form of large perfect crystals. Two drops, joining after incipient crystallisation, might assume the not uncommon form of interpenetrating twin crystals. Illustrations of all these caprices are here to-night.

Again, diamond crystals are generally perfect on all sides. They show no irregular side or face by which they were attached to a support, as do artificial crystals of chemical salts; another proof that the diamond must have crystallised from a dense liquid.

Having no double refraction, the diamond should not act on polarised light. But, as is well known, if a transparent body which does not so act is submitted to strain of an irregular character it becomes doubly refracting, and in the polariscope reveals the existence of the strain by brilliant colours arranged in a more or less defined pattern according to the state of tension in which the crystal exists. I have examined many hundred diamond crystals under polarised light, and with few exceptions all show the presence of internal tension. I will project some diamonds on the screen by means of the polarising microscope, and you will see by the colours how great is the strain to which some of them are exposed. On rotating the polariser, the black cross most frequently seen revolves round a particular point in the inside of the crystal; on examining this point with a high power, we sometimes see a slight flaw, more rarely a minute cavity. The cavity is filled with gas at enormous pressure, and the strain is set up in the stone by the effort of the gas to escape. I have already told you that the great Cullinan diamond by this means reveals a state of internal stress and strain.

It is not uncommon for a diamond to explode soon after it reaches the surface; some have been known to burst in the pockets of the miners or when held in the warm hand, and the loss is the greater because large stones are more liable to explode or fly in pieces than small ones. Valuable stones have been destroyed in this way, and it is whispered that cunning dealers are not averse to allowing responsible clients to handle or carry in their warm pockets large crystals fresh from the mine. By way of safeguard against explosion, some dealers imbed large diamonds in raw potato to ensure safe transit to England.

The anomalous action which many diamonds exert on polarised light is not such as can be induced by heat, but it can easily be conferred on diamonds by pressure, showing that the strain has not been produced by sudden cooling, but by sudden lowering of pressure.

The illustration of this peculiarity is not only difficult, but sometimes exceedingly costly—difficult because it is necessary to arrange for projecting on the screen the image of a diamond crystal between the jaws of a hydraulic press, the illuminating light having to pass through delicate optical polarising apparatus—and costly because only perfect, clear crystals can be used, and crystals of this character sometimes fly to pieces as the pressure rises. No colour as yet is seen on the screen, the crystal not being birefringent. A movement of the handle of the press, however, gives the crystal a pinch, instantly responded to by the colours on the screen, showing the production of double refraction. Another movement of the handle brightens the colours; a third may strain the crystal beyond its power of resistance, so I refrain.

Hardness.

Diamonds vary considerably in hardness, and even different parts of the same crystal differ in their resistance to cutting and grinding.

Beautifully white diamonds have been found at Inverel, New South Wales, and from the rich yield of the mine and the white colour of the stones, great things were expected. In the first parcel which came to England the stones were found to be so much harder than South African diamonds that it was at first feared they would be useless except for rock-boring purposes. The difficulty of cutting them disappeared with improved appliances, and they now are highly prized.

The famous Koh-i-noor, when cut into its present form, showed a notable variation in hardness. In cutting one of the facets near a yellow flaw, the crystal became harder and harder the further it was cut, and after working the mill for six hours at the usual speed of 2400 revolutions a minute, little impression was made. The speed was increased to more than 3000, when the work slowly proceeded. Other portions of the stone were found to be comparatively soft, and hardened as the outside was cut away.

I can illustrate the intense hardness of the diamond by experiment. On the flattened apex of a conical block of steel I place a diamond, and upon it I bring down a second cone of steel. With the lamp I project an image of the diamond and steel faces on the screen, and force them together by hydraulic power. I can squeeze the stone into the steel blocks without injuring it in the slightest degree.

The pressure gauge shows 60 atmospheres, and the piston being 3·2 inches diameter, the absolute pressure is 3·16 tons, equivalent on a diamond of 12 square mm. surface to 170 tons per square inch of diamond.

Although not directly bearing on the subject, I will introduce the only serious rival of the diamond as regards hardness. It is the metal tantalum, a fine specimen of which I owe to Messrs. Siemens Brothers. A hole had to be bored through a plate of this metal, and a diamond drill was used revolving at the rate of 5000 revolutions per minute. This whirling force was continued ceaselessly for three days and nights, when it was found that only a small depression ¼ mm. deep had been drilled, and it was a moot point which had suffered most damage, the diamond or the tantalum.[1] In another respect tantalum is likely to rival graphitic carbon, as it has rivalled adamantine carbon. Its thin wire is extensively used for filaments of incandescent electric lamps; it shows a much higher efficiency than does the old carbon filament. The melting point of tantalum is about 2300° C., a temperature seldom or never reached in an ordinary lamp.

Refractivity.

But it is not the hardness of the diamond so much as its optical qualities that make it so highly prized. It is one of the most refracting substances in nature, and it also has the highest reflecting properties. In the cutting of diamonds advantage is taken of these qualities. When cut as a brilliant the facets on the lower side are inclined so that light falls on them at an angle of 24° 13′, at which angle all the incident light is totally reflected. A well cut brilliant should appear opaque by transmitted light except at a small spot in the middle where the table and culet are opposite. All the light falling on the front of the stone is reflected from the facets, and the light passing into the diamond is reflected from the interior surfaces and refracted into colours when it passes out into the air, giving rise to the lightnings, the effulgence, and coruscations for which the diamond is supreme above all other gems.

In vain I have searched for a liquid of the same refrac-

[1] W. von Bolton *Zeitschr. Elektrochem*, ii., 45–51, January 20, 1905.

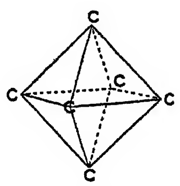
tion as diamond. Such a liquid would be invaluable to the merchant, as on immersing a stone the clear body would absolutely disappear, leaving in all their ugliness the flaws and black specks so frequently seen even in the best stones.

Arguing from theoretical considerations connected with the specific refractive energy of diamond, and employing Lorentz's expression for refraction—

$$\left(\frac{\mu^2-1}{\mu^2+2}\right)\left(\frac{P}{d}\right),$$

in which μ=refractive index, $\mu-1$=refractive energy, d=density, and P=molecular weight, Brühl has shown that diamond is perfectly normal in its optical properties, and has an atomic refraction =5. He has put forward the speculation that the diamond may be the last member of the paraffin series of which marsh-gas is the first.

"Now we can imagine," says Brühl,[1] "why the diamond, *i.e.* pure crystallised carbon, is optically normal. We obtain an idea of the mineral's chemical constitution, and of the way in which the atoms of carbon are perhaps combined in the sparkling gem. The diamond cannot possibly contain any double bonds. Imagine, however, at each of the six corners of a regular octahedron, a single molecule of marsh-gas, CH_4, *i.e.* altogether C_6H_{24}, and then imagine all the 24 hydrogen atoms successively removed, so that each carbon atom is connected with each of its neighbours only by a single bond, and thus all six atoms of carbon are united together in a single whole. Then you obtain, as the most simple representation of the molecule of the diamond, a regular octahedron, with one atom of carbon at each of its six corners, whilst the edges represent the mutual bonds:—



Several simple molecules of this kind may be combined into one crystallised particle of the spectrochemically normal diamond."

Absorption Spectrum of Diamond.

On passing a ray of light through a diamond and examining it in a spectroscope, B. Walter has found in all colourless brilliants of more than one carat in weight an absorption band at wave-length 4155 (violet). He ascribes this band to an impurity, and suggests it may possibly be due to samarium. Three other fainter lines were detected in the ultra-violet by means of photography.

Phosphorescence of Diamond.

After exposure for some time to the sun many diamonds glow in a dark room. Some diamonds are fluorescent, appearing milky in sunlight. In a vacuum, exposed to a high-tension current of electricity, diamonds phosphoresce of different colours, most South African diamonds shining with a bluish light. Diamonds from other localities emit bright blue, apricot, pale blue, red, yellowish green, orange, and pale green light. The most phosphorescent diamonds are those which are fluorescent in the sun. One beautiful green diamond in my collection, when phosphorescing in a good vacuum, gives almost as much light as a candle, and you can easily read by its rays. But the time has hardly come when diamonds can be used as domestic illuminants! The emitted light is pale green, tending to white, and in its spectrum, when strong, can be seen bright lines, one at about λ 5370 in the green, one at λ 5130 in the greenish blue, and one at λ 5030 in the blue.

After many years' bombardment in a vacuum tube this diamond grew very dark, almost black, on the surface. Heating in a mixture of nitric acid and potassium chlorate scarcely changed the colour. The action of heat was then tried, and on slowly heating to about 500° C. the dark colour entirely disappeared, and the original milky green appearance was restored. Although I watched narrowly I could see no trace of phosphorescence during the heating.

Diamonds which phosphoresce red generally show the yellow sodium line superposing on a continuous spectrum. In one Brazilian diamond phosphorescing a reddish yellow colour, I detected the citron line characteristic of yttrium.

By permission of Mrs. Kunz, wife of the well known New York mineralogist, I will show you perhaps the most remarkable of all phosphorescing diamonds. This prodigy diamond will phosphoresce in the dark for some minutes after being exposed to a small pocket electric light, and if rubbed on a piece of cloth a long streak of phosphorescence appears.

Tribo-luminescence.

A few minerals give out light when rubbed, and Mrs. Kunz's diamond is equally striking in this respect. In the year 1663, the Hon. Robert Boyle read a paper before the Royal Society, in which he described several experiments made with a diamond which markedly showed tribo-luminescence. As specimens of tribo-luminescent bodies, I show you sphalerite (sulphide of zinc) and an artificial sphalerite, which is even more responsive to friction than the native sulphide.[1]

Combustion of the Diamond.

When heated in air or oxygen to a temperature varying from 760° C. to 875° C., according to its hardness, the diamond burns with production of carbonic acid. It leaves an extremely light ash, sometimes retaining the shape of the crystal, consisting of iron, lime, magnesia, silica, and titanium. In boart and carbonado the amount of ash sometimes rises to 4 per cent., but in clear crystallised diamonds it is seldom higher than 0·05 per cent. By far the largest constituent of the ash is iron.

Action of Radium on Diamond.

The β rays from radium having like properties to the stream of negative electrons in a radiant matter tube, it was of interest to ascertain if they would exert a like difference on diamond. The diamond glows under the influence of the β radiations, and crushed diamond cemented to a piece of card or metal makes an excellent screen in a spinthariscope—almost as good as zinc sulphide. Some fine colourless crystals of diamond were embedded in radium bromide and kept undisturbed for more than twelve months. At the end of that time they were examined. The radium had caused them to assume a beautiful blue colour, and their value as "fancy stones" had been materially increased. Here are a couple of diamonds originally of the same purity of water. One has been coloured by radium, the other is in its natural state. The colour of the radium-tinted stone is very pronounced. The lantern slide shows the darkening thus produced. A and B are diamonds after twelve months' burial in radium bromide; diamond C is of the original colour.

This blue colour is persistent, and penetrates below the surface. It is unaffected by long-continued heating in strong nitric acid and potassium chlorate, and is not discharged by heating to redness.

To find out if this prolonged contact with radium had communicated to the diamond any radio-active properties, six diamonds were put on a photographic plate, and kept in the dark for a few hours. I will project the image of the result after development. The three on the upper row are the diamonds which have had a prolonged sojourn with radium, the three below are similar diamonds picked out for comparison, which have not been near radium. See how strangely the three upper ones have acted. Notice also that by mere contiguity to the others the lower diamonds also shine with an induced, factitious radio-activity. I throw on the screen a magnified image of one of the blue crystals, and you see in how regular and geometrical a pattern the radio-active emanations radiate from the crystal. This observation has only been made

Manganese sulphate	½ per cent.

Mix with distilled water and dry at a gentle heat. Put in luted crucible and keep at a bright red heat for from two to three hours.

a short time, and is still under investigation. Like the blue tint, the radio-activity persists after drastic treatment. To me this proves that radio-activity does not merely consist in the adhesion of electrons or emanations given off by radium, to the surface of an adjacent body, but the property is one involving layers below the surface, and like the alteration of tint is probably closely connected with the intense molecular excitement the stone had experienced during its twelve months' burial in radium bromide.

A diamond that had been coloured blue by radium, and had acquired strong radio-active properties, was slowly heated to dull redness in a dark room. Just before visibility a faint phosphorescence spread over the stone. On cooling and examining the diamond, it was found that neither the colour nor the radio-activity had suffered appreciably.

The diamond is remarkable in another respect. It is extremely transparent to the Röntgen rays, whereas highly refracting glass, used in imitation diamonds, is almost perfectly opaque to the rays. I exposed for a few seconds over a photographic plate to the X-rays the large Delhi diamond of a rose-pink colour weighing 31½ carats, a black diamond weighing 23 carats, and a glass imitation of the pink diamond. On development, the impression where the diamond obscured the rays was found to be strong, showing that most rays passed through, while the glass was practically opaque. By this means imitation diamonds can readily be distinguished from true gems.

I have already signified that there are various degrees of refractoriness to chemical reagents among the different forms of graphite. Some dissolve in strong nitric acid; other forms of graphite require a mixture of highly concentrated nitric acid and potassium chlorate to attack them, and even with this intensely powerful agent some graphites resist longer than others. M. Moissan has shown that the power of resistance to nitric acid and potassium chlorate is in proportion to the temperature at which the graphite was formed, and with tolerable certainty we can estimate this temperature by the resistance of the specimen of graphite to this reagent.

The superficial dark coating on a diamond after exposure to molecular bombardment I have proved to be graphite.[1] M. Moissan[2] has shown that this graphite, on account of its great resistance to oxidising reagents, cannot have been formed at a lower temperature than 3600° C.

It is thus manifest that the bombarding electrons endowed with an electric charge, and striking the diamond with enormous velocity, raise the superficial layer to the temperature of the electric arc, and turn it into graphite, whilst the mass of diamond and its conductivity to heat are sufficient to keep down the general temperature to such a point that the tube appears scarcely more than warm to the touch.

A similar action occurs with silver, the superficial layers of which can be raised to a red heat without the whole mass becoming more than warm.[3]

I will now direct your attention to a strange property of the diamond, which at first sight might seem to discount the great permanence and unalterability of this stone. It has been ascertained that the cause of phosphorescence is in some way connected with the hammering of the electrons, violently driven from the negative pole, on to the surface of the body under examination, and so great is the energy of the bombardment that impinging on a piece of platinum or even iridium the metal will actually melt. When the diamond is thus bombarded in a radiant matter tube the result is startling. It not only phosphoresces, but assumes a brown colour, and when the action is long-continued becomes almost black.

I will project a diamond on the screen and bombard it with radiant matter before your eyes. I do not like to anticipate a failure, but I am at the mercy of my diamond. I cannot rehearse this experiment, and it may happen that the diamond I have selected will show caprice and not blacken in reasonable time. Some diamonds visibly darken in a few minutes, while others, more leisurely in their ways, require an hour.

This blackening is only superficial, but no ordinary means of cleaning will remove the discoloration. Ordinary oxidising reagents have little or no effect in restoring the colour. The black stain on the diamond is due to a form of graphite which is resistant to oxidation.

Conversion of Diamond into Graphite.

Although we cannot convert graphite into diamond, we can change the diamond into graphite. I take a clear crystal of diamond and place it between two carbon poles, and throw the image on the screen by means of a powerful arc lamp behind. I now bring the poles with intervening diamond together and form an arc between. The temperature of the diamond rapidly rises, and when it approaches 3600° C., the vaporising point of carbon, it breaks down, swells, and changes into black and valueless graphite. I show this experiment because it is striking and suggestive. I may add that it is costly—because the stone, if not of fine quality, might easily burst.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

SIR CLEMENTS R. MARKHAM, K.C.B., F.R.S., will deliver an address at Cambridge on Thursday, October 19, introductory to the courses of instruction in geography.

Science announces the death of General Isaac J. Wistar, of Philadelphia, founder of the Wistar Institute of Anatomy and Biology of the University of Pennsylvania, formerly president of the American Philosophical Society. By his will the Wistar Institute will receive the residue of his estate, thought to amount to about 80,000*l*.

IN the course of an address to the students of Cornell University in 1903, President Schurman emphasised the necessity of a systematic distribution of the daily time of college students. He recommended the following general apportionment of hours:—for work, eleven; for sleep, eight; for amusement, one; for meals and athletics, two hours each. Work is made to include not only time spent in the laboratory and lecture-room and in private study, but also time given to societies and to self-support. This advice led Dr. Guy M. Whipple, of Cornell University, to try to ascertain how the students in his university actually do distribute their daily time. The results of his inquiries are described in an article in the current number of the *Popular Science Monthly*. In the summary to the detailed tables given in his article Dr. Whipple states that, taking the university as a whole, the average Cornell student devotes just nine hours daily to college work, sleeps 7·9 hours, devotes 2·23 hours to amusement, 1·72 hours to physical exercise, 1·4 hours to meals, 0·39 hour to self-support, and 1·36 hours to unclassified activities. The average length of time given to work is greatest in the college of medicine, and progressively less in those of engineering, law, agriculture, and arts. Both in the university at large and within the College of Arts and Sciences, men give more time to college work than women.

PROF. J. W. JUDD, F.R.S., distributed on October 5 the medals and prizes gained during the past session by the students of the Royal College of Science, London, in the lecture theatre of the Victoria and Albert Museum, South Kensington. The Dean, Prof. Tilden, F.R.S., in opening the proceedings, referred with regret to several losses which the college and school had sustained during the year, alluding particularly to the death of Prof. Howes. The geological division had lost its chief by the retirement of Prof. Judd. The college is now, the Dean continued, in an attitude of expectancy in regard to the future, and it is possible that next year they will be able to hold the prize distribution in the new buildings. He said that in ten years seventy-six of the students of the college have taken the degree of B.Sc., and, in addition, thirty have taken first-class honours, besides which there are nine doctors of science. Prof. Judd, having distributed the awards, addressed the students. He acknowledged the uniform courtesy and consideration which he had received from colleagues and students alike during his forty-five years' experience in connection with the school. Nearly two-thirds of that period had been spent in the position of one of the teachers. He congratulated them on the expansion and development which is now promised, and expressed the hope that the change would lead to even

greater successes in the future than have been attained in the past. Mr. R. L. Morant, permanent secretary of the Board of Education, in moving a vote of thanks to Prof. Judd, said the college stood for the essential necessity of practical work as a proper means of the study of science.

THE new College of Hygiene and Physical Training instituted by the Carnegie Dunfermline trustees, which was described in our issue for September 28 (p. 550), was opened formally on October 4 by Lord Linlithgow, Secretary for Scotland and vice-president of the Council of Education in Scotland. The chairman, Dr. John Ross, delivered the opening address. He said the work of the college is to be two-fold. Following the method established for the training of the teachers in elementary schools, there is provided first what may be called a great practising school with 4500 pupils, consisting of all the school children, and next there is the college proper, consisting of young women prepared to adopt the teaching of physical culture as a profession, or to acquire for their own personal benefit a knowledge of themselves and the most rational rules of life. As yet only young women are to be received, but it is anticipated that it will be possible in the near future to receive young men. Lord Linlithgow, during the course of an interesting speech, said there is no doubt that the country is waking up to the necessity of some sort of physical training for young people, and to the necessity of a better understanding of the laws of hygiene. It is well that the public should understand what physical training means. Lord Linlithgow defined it as the careful development of the general health to the advantage of the whole body, and indirectly to the advantage of the mind. The Carnegie trustees are, he continued, doing a great and valuable service to Scotland in taking up this subject. They are doing a work which no school board can do, for it is doubtful whether public opinion has as yet ripened sufficiently to allow the Education Department to apply any considerable portion of the national funds to a purpose of this kind. It will come in time, for the public is taking an increasing interest in all that concerns the feeding, the management, the cleanliness, and physical welfare of the young generation. It is being recognised more and more that the amount of information, or book-learning, which a child acquires at school is a matter of comparatively little importance. What is wanted is the healthy training of the boy or girl both physically and mentally.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, July 14.—"The Phagocytosis of Red Blood-cells." By Dr. J. O. Wakelin **Barratt**. Communicated by Sir Victor Horsley, F.R.S.

The author has investigated the conditions under which phagocytosis of red blood-cells, by means of leucocytes, is brought about. Metchnikoff, who studied this process, attached great importance to the part played by the leucocytes, but Sawtchenko discovered that the chief factor in the production of this form of phagocytosis is sensibilisation of the red blood-cells, which can be brought about by the serum of animals which have been previously injected with the variety of red blood-cells employed for phagocytosis, and he attributed the action of the serum to the presence of amboceptor (immunisine, fixateur). That this is not so, however, is shown by the circumstance that, in the absence of amboceptor, strongly marked phagocytosis may be brought about by serum, and further experiments showed that the effective constituent is an opsonin. In addition, it was found that erythrocytic opsonins are sometimes present, usually in relatively small quantities, in normal sera, and in suitably chosen conditions of experiment may be used to prepare red blood-cells for ingestion by leucocytes.

PARIS.

Academy of Sciences, October 2.—M. Troost in the chair.—Summary of the observations of the solar eclipse of August 29–30 made at Sfax, Tunis: G. **Bigourdan.** Light clouds were present during the eclipse, but were not sufficiently numerous to interfere seriously with the observations. Particulars are given of the determination of time, the observations of the contacts, the photography of the inner corona, the monochromatic photography of the corona, the work done with the spectrographs, ocular and photographic photometry, the influence of the passage of the shadow on the magnetic state of the earth, meteorology and actinometry, drawings made with the naked eye, observation of the moving shadows, the darkness during the eclipse, and the visibility of the stars.—On the laws of sliding friction: Paul **Painlevé.** An extension of the results obtained in a previous paper and a reply to some objections.—Observation of the eclipse of the sun of August 30 at the Observatory of Marseilles: M. **Stéphan.** The atmospheric conditions were quite satisfactory. The times of first and second contact are given, and the changes of temperature were automatically registered.—On some differential equations of the second order: Richard **Fuchs.**—On minimum surfaces: S. **Bernstein.**—Experimental verifications of the undulatory form of the photographic function: Adrien **Guébhard.**—On isostrychnine: A. **Bacovesco.** Isostrychnine is obtained hy heating strychnine with water in sealed tubes at 160° C. to 180° C. The colour reactions of the isomer resemble those of the original alkaloid, but there are points of difference. The poisonous properties of the isomer are less marked than in strychnine, and, indeed, rather approximate to those of curare. That the two alkaloids are structurally different is shown by the action of sodium ethylate, which converts isostrychnine integrally into the isostrychnic acid of Tafel. —On the mode of propagation of some aquatic plants: Louis **François.**—On the geology of the Sahara: R. **Chudeau.**—On the direction of the permanent magnetisation of a metamorphic clay from Pontfarlin (Cantal): Bernard **Brunhes.**

MECHANICS FOR STUDENTS.

Mechanics: a School Course. By W. D. Eggar, Pp. viii+288. (London: Edward Arnold, 1905.) Price 3s. 6d.

Elements of Mechanics. By Prof. Mansfield Merriman. Pp. 172. (New York: John Wiley and Sons; London: Chapman and Hall, Ltd., 1905.) Price 1 dollar net.

An Intermediate Course of Mechanics. By A. W. Porter. Pp. viii+422. (London: John Murray.) Price 5s.

MR. EGGAR is doing good work in the movement which aims at the extension of quantitative measurements in the courses of mathematical studies for youths, and a school book of mechanics from the author of the well known experimental introduction to geometry is sure to be received with favour and interest by teacher and pupil alike. We may say at once that readers are not likely to be disappointed, for the experimental work on which the fundamental principles are based is simple, suggestive, and thorough, and the essence of the subject is not obscured by an undue amount of mathematical dressing.

The first five chapters are concerned with the verification and elucidation of Newton's laws of motion, and some very efficient apparatus is introduced and described in this admittedly difficult portion of the subject; we agree with the author that "velocities, accelerations, moments, work, and momentum can be made clear to a student if he has to measure them." Experiments of Galileo by means of which the laws of falling bodies were discovered are introduced with suitable modifications; a clever method of measuring time by the use of a vibrating spring carrying a paint brush (due to Mr. Fletcher) is employed, and altogether this section, treating kinetics experimentally, is most interesting and very satisfactory. The next five chapters relate to statics and the equilibrium of forces, and the remaining portion of the book deals with work, friction, simple machines, projectiles, circular and simple harmonic motions, stress and strain, and fluids.

There is little in the book to which exception can be taken. When the author seems to imply that the unit of force in the "engineer's" system is a variable quantity, he appears to misapprehend the system. The experiments on change of motion are confined to straight-line motion. The student would have been led to a more comprehensive view of the subject if there could have been introduced an experiment illustrating vector change in plane motion, accompanied by the plotting of a hodograph. Then, instead of resorting to an antiquated and non-instructive proof for the acceleration in uniform circular motion, the hodograph could have been used to illuminate the principle that force is the time rate of change of momentum.

The test is arranged so that statics can be taken before kinetics if this procedure is thought desirable, but the sequence adopted by Mr. Eggar seems to us the right one. In addition to the experimental work, numbers of good and suggestive exercises are provided at appropriate intervals. The author has succeeded in producing a most admirable text-book, and one which we should like to see largely used throughout the schools of the country.

The aim of Prof. Merriman in his volume is to introduce mechanics to young engineering students in a manner whereby the principles are established by constant appeals to experience, and are not lost sight of by the introduction of a mass of algebraical matter. The intention is good, but the experience should be that gained first-hand by the student himself from experimental work in a laboratory. The method employed by the author is to base the science on axioms which the reader has to take largely on trust. After the first four pages, six of these are suddenly introduced. Thus:—"*Axiom* 1. Where only one force acts on a body, it moves in a straight line in the direction of that force."

As a professor of civil engineering, the author naturally gives more attention to statics than to dynamics. In fact, the latter branch is very feebly presented, and the subject does not gain by the substitution of the axioms for Newton's laws. For example, the fundamental principle that impulse is equal to change of momentum is nowhere found. For the acquirement of a knowledge of the subject reliance is largely placed on the working of the four hundred problems, mostly numerical, which are spread over the book.

In Prof. Porter's elementary text-book of theoretical mechanics the subject is presented so as to appeal to physicists rather than to engineers. Students reading for the intermediate pass examination of London University will find the book very helpful. A few experiments in verification of the laws of mechanics are described, but the treatment is almost wholly deductive. The author begins by discussing the kinematics and kinetics of the rectilinear motion of a rigid body, and is very happy in his explanations of the fundamental conceptions of space, time, mass, momentum, &c., particular attention being paid to the units of measurement and to the change from one set of units to another. In defining the several systems, however, the author seems to be mistaken in his view that the unit of force adopted by engineers is a variable one depending upon latitude.

The consideration of the mechanics of a particle is preceded by a chapter on the addition of vectors, in which some elementary trigonometry is introduced. The author might here have improved his definitions of the trigonometrical ratios for angles of any magnitude by making use of the projections of a rotation vector. The action of couples and the dynamics of rigid bodies having plane motion are next considered, and very logically, but here a few additional experiments personally carried out would have materially added to the student's grip of this somewhat difficult part of the subject. There is a chapter dealing mathematically

with some simple mechanical contrivances such as the wedge, screw, lever, and pulley; another on simple harmonic motion, in which the pendulum is rather fully dealt with; and then follows a chapter devoted to the mechanics of fluids, and comprising an examination of the stability of floating bodies. The book concludes with a chapter on units and dimensions.

Sets of examples are given, the numerical answers being collected at the end of the volume. Specimens of recent intermediate science examination papers of University College in connection with the University of London are appended. Some will regret that the author does not assume a slight acquaintance with the Calculus such as must be possessed by most readers of the book. But taken altogether the subject is dealt with very thoroughly, and developed naturally and logically, and the book deserves a wide circulation.

MUSIC OF SINGING-BIRDS.

Field Book of Wild Birds and their Music. By F. Schuyler Mathews. Pp. xxxv+262. (New York and London: G. P. Putnam's Sons, 1904.) Price 2 dollars.

THIS is a very pretty little book, with many charming illustrations of American singing-birds, and numerous attempts to represent their songs in our musical notation. It would seem as if the songs of American birds lent themselves more readily than those of our European species to such notation, for this is by no means the first attempt of this kind which has recently been made on the other side of the water. The present reviewer is under the disadvantage of not having heard these birds in their native land, and is quite ready to believe that Mr. Mathews's musical notations may give an American some vague idea of what his birds sing; at the same time, as one whose knowledge of music is even older than his knowledge of birds, he must emphatically express a hope that British ornithologists will not imitate their American brethren in trying to render our familiar songs on this system. Our music is a highly artificial product, subject to strict limitations which have gradually been placed upon it as the art has developed in the course of many centuries; and to attempt to catch and (so to speak) to tame the songs of wild birds, bringing them forcibly under conditions which entirely deprive them of their natural freedom in regard to pitch, scale, time, and rhythm, is in almost all cases to do them cruel violence. A very few of our birds—the cuckoo, for example, and the song-thrush—have vocal utterances which can be expressed on our musical scale; but by far the greater number can only be represented in the amusing way in which Mr. Mathews has noted the song of the bobolink on pp. 50 and 51—by a cloudy jumble of notes and lines above the stave, which suggests a flute-player gone mad.

The sentence which he has prefixed to this curious bit of notation really explains his object and method, and forbids us to take him too scientifically. He says, "If one prefers not to *interpret* bird-music, but to take it from Nature exactly as it comes, this bit that follows may prove acceptable." What he has really been trying to do, it seems, is to *interpret* bird-music, by which he means that he has listened to it with a musical mind, and has gained from it certain musical impressions, which he again interprets to us in the language of our musical art, not only in the form of melody confined in the fetters of our musical scale, but in many cases enriched with ingenious accompanying harmonies. The reader will find a good illustration of this method in the treatment of the song of the American song-sparrow, pp. 110 foll. It is the method pursued by all who seriously attempt to transfer the notes of birds to music-paper, though it may be doubted whether they would all acknowledge this as frankly as Mr. Mathews. It follows that our knowledge of bird-music is not really increased by these efforts, charming and interesting as they often are to the musician; for what is put upon paper is not the song of the bird, but an interpretation of it by an artistic mind. Taken in this light, this little book may give much pleasure, and may add a good deal to our knowledge of some delightful American songsters.

W. W. F.

OUR BOOK SHELF.

Studien ueber Hautelektricität und Hautmagnetismus des Menschen. By Dr. Erik Harnack. Pp. 65. (Jena: Gustav Fischer, 1905.) Price 1.60 marks.

THE author takes a pocket-compass, about the size of a lady's watch, with metal case and watch-glass top, and having placed it on a level surface lightly rubs the glass with the tip of his finger. The needle is immediately deflected from the magnetic meridian, remaining so for a minute or more, and then returning to its original position. That magnetism has nothing to do with it is shown by the fact that the same phenomenon occurs when for the magnet there is substituted a needle of nickel, platinum, zinc, bismuth, or ivory, although the absence in such cases of a directive force makes it more difficult to observe. Static charges, apparently much stronger, are without effect. Some people can influence the needle much more than others, and the author's power is not always equally strong.

Quantitative experiments were undertaken by the author to measure the E.M.F. induced by rubbing a glass plate of the same size and shape in the same manner. Using a Braun electrometer graduated up to 1500 volts, the maximum value obtained by him was 1300 volts. It seems evident that a strong electric charge is developed on a part of the glass surface by the friction of the finger upon it, and that the needle being free to move, and, moreover, in metallic connection with the case, is attracted by the charged surface.

This is not disputed by the author, his contention being that the magnitude of the effect is out of all proportion to the force expended, and that, therefore, it is not due to physical but to physiological causes set in action by the slight friction of the finger-tips. In the present writer's opinion this contention is certainly not substantiated. The total energy of the charge of a condenser composed of a compass-needle and a square centimetre or so of glass with a P.D. of a thousand or, for that matter, of ten thousand volts is trifling, and since the work actually done consists in the mere turning of the needle through 90°, one is driven to ask whether if a cocoon fibre were attached to the end of the needle and to the

operator's finger he would be able to feel the pull of the earth's magnetic force upon it. The work done by a few light touches of the finger must be amply sufficient to furnish all the energy required to deflect the needle. But to a modern electrician it certainly seems a remarkably efficient transformation.

GEORGE J. BURCH.

An Introduction to the Study of Colour Phenomena. By Joseph W. Lovibond. Pp. 48; 10 coloured plates. (London: E. and F. N. Spon, Ltd.; New York: Spon and Chamberlain, 1905.) Price 5s. net.

THE author states that his object has been to supply the long-felt want of a power of recovering a given colour sensation and of a colour nomenclature by which that sensation may be quantitatively described. To this end "scales of red, yellow and blue were constructed of glass slips, the slips of each scale being all of one colour with a regular variation in intensity from 0.01 to 20 units, equal units of the three scales being in colour equivalence with each other. . . . The test of equivalence is that a white light viewed through equal units of the three scales should give no evidence of colour. . . . The fogs on Salisbury Plain furnished the light actually used." It was found that red, yellow, and blue were the only colours suitable for systematic work, and that any colour could be produced by their combination. The dimensions of the unit are, it is said, necessarily arbitrary, but the scale-divisions are equal, while the unit itself is recoverable.

The colour to be tested is matched by that of the light transmitted by one of the glasses, or by several superposed, equality of luminosity being secured, when necessary, by the interposition of a neutral-tinted combination between the eye and the coloured object. A specification of the glasses employed is registered, according to certain rules, as a formula which defines in terms of the author's constants the colour "developed," and supplies data for its future reproduction.

To those who are accustomed to regard the spectrum as the natural basis of colour experiment the author's method cannot but appear crude and unscientific; but, given a sufficient supply of carefully selected glasses, it is probable that much useful work might be done in a rough and ready way by its means. An example occurs in the quantitative study of the colour of the human blood in health and in disease, which is illustrated in plate vi.

The book concludes with an exposition of Mr. Lovibond's new theory of colour.

Index Phytochemicus. By Drs. J. C. Ritsema and J. Sack. With introduction by Dr. M. Greshoff. Pp. 86. (Amsterdam: J. H. de Bussy.)

DR. GRESHOFF explains in the introduction to this volume that it originated in a card index to the literature of plant chemistry compiled for use in the laboratory of the Colonial Museum at Haarlem, where the work carried on consists principally of the investigation of the proximate constituents of plants.

The index enumerates the names of more than two thousand plant constituents, and gives in each case the percentage composition, formula, melting or boiling point, and at least one reference to the literature —usually Beilstein's "Handbuch," though in a few cases the references are to original papers. The volume also contains a short but useful bibliography of plant chemistry.

The information given in the tables, so far as can be judged from trials in a few cases, appears to be accurate, and the index should prove useful to chemists engaged in the investigation of plant products.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Eclipse Predictions.

IT is always interesting to compare the results of observation with those predicted by calculation. In the case of the recent total eclipse of the sun this is rendered difficult by the want of agreement in the predictions of the two most used authorities, the Nautical Almanac and the Connaissance des Temps. The discrepancies in the predicted duration of totality and of the breadth of the band traced on the earth's surface by the total phase are made apparent in the following table. It is compiled from the table in the Nautical Almanac headed "Limits of total phase of the Solar Eclipse," and the corresponding table in the Connaissance des Temps entitled "Limites de l'Éclipse totale et Durée de la Phase totale sur la Ligne centrale." Entries for as nearly as possible the same time in each table have been taken and are placed together:—

Column A contains the authority, Nautical Almanac (N.A.) or Connaissance des Temps (C.T.).

Column B contains the time (G.M.T.) for which each prediction is made.

Column C contains the calculated distance (in nautical miles) and the bearing of the northern limit of totality from the corresponding southern limit.

Column D contains the durations of totality on the central line as predicted by the one authority and (in brackets) as interpolated from the prediction of the other.

Column E contains the differences of these pairs of values.

It will be seen that, for stations in Spain and the adjacent Mediterranean, the duration of totality on the central line was predicted by the French authority to be from seven to eight seconds longer than by the British authority. In the same region, the width of the band of totality is from ten to eleven nautical miles greater by the French than by the British prediction. The orientation of the line connecting the two limits of totality also differs considerably in the two tables.

It is reported that at Sousse and Gabes, two towns in Tunisia, the eclipse was partial, while a total eclipse had been predicted for them. The prediction for these places would surely rest on French authority; we are therefore entitled to conclude that the mistake has been made by the French calculators. An excessive estimate of the width of the band of totality would almost certainly be accompanied by an excessive estimate of the duration of totality, and the table shows that both estimates are considerably greater in the Connaissance des Temps than in the Nautical Almanac.

J. Y. BUCHANAN.

October 13.

Absence of Vibration in a Turbine Steamship.

RETURNING homeward to Paris the middle of September from the Tripoli eclipse, and finding passage to America difficult to obtain, I chanced to learn that the triple-screw turbine steamer R.M.S. *Virginian* was sailing from Liverpool for Montreal on September 30, so I was very glad to have the opportunity of a voyage in a ship full powered with this novel type of propulsion. After a week on board I have no hesitation in saying that for freedom from

the nerve-annoying tremors incident to the usual reciprocating engines, the *Virginian* has proved far and away the quietest steamship I have ever voyaged on. Excellent evidence of this, I think, lies in the exceptionally large number of passengers who dined comfortably in the saloon at the roughest period of our entire passage. There was a fairly heavy sea on, and the ship was by no means free from wave-origined motion. So I am quite of the opinion that sea-sickness and all its train of discomforts must be greatly aggravated by the engine-borne tremors of the ordinary steamship, and that many people who are delicate sailors under ordinary conditions might take ocean journeys with comparative comfort in a turbined ship.

So unostentatious are the rotary engines of the *Virginian,* let alone their occupying but one-fourth the space of the usual expansion engines, that the quietness of their powerful and effective working, in every part of the ship, was continually deceiving one into thinking that the vessel had lost headway, or might have come to anchor altogether. Especially was this true in the dining saloon, that most critical of all spots, where one could rarely detect so much as a ripple on water in a glass, although going ahead at full speed of 15 knots.

To my mind the *Virginian* seemed to behave all the voyage quite as if her motive power were entirely without her; in fact, she could scarcely have ridden more smoothly, or with less of that exasperating vibration (the unceasing action of which, I am convinced, is a prominent factor in inducing *mal de mer*), if she had been towed at the identical speed by a huge hawser. DAVID TODD.

R.M.S. *Virginian*, Straits of Belle Isle, October 4.

A Parasite of the House-fly.

REVERTING to the recent correspondence under this heading between Mr. Davenport Hill and Prof. Hickson (NATURE, August 24 and 31), I recall that a few years back many house-flies with Chelifers attached were sent to me at the Natural History Museum for determination of the species and explanation of the phenomenon. The first task was as easy as the second was difficult. The Chelifer was in most, nay in all, cases, so far as my memory serves, *Chernes nodosus.* But those who suggest that the explanation is to be sought and found in the value of the habit as a means of securing dispersal hardly realise, I think, the difficulties in the way of its acceptance. Chelifers are minute, active, and, for arthropods, not exceptionally prolific. Hence the sufficiency of "elbow-room" for the survivors of a family of, say, forty, on the site chosen by the female for her progeny does not coincide with the view that they have special need of transportation. Moreover, when we remember that a Chelifer attached to a fly is exposed to the danger of being killed by the enemies of that insect, and also to the great chance of being landed in a wholly unsuitable environment, it can hardly be maintained that the advantage derived from this method of dispersal has been a sufficiently important factor in survival to preserve and foster an initial instinct to grab and hang on to the legs of flies. That the aërial porterage thus secured, whether fortuitously or "intentionally," must be a means of dispersal is too obvious to dispute; but I do not think more than that can be claimed for it, since it is as likely to end in failure as in success.

Chelifers may be found not uncommonly beneath the wing-cases of large beetles. Presumably this habitat has been adopted for the sake of the food supplied by the parasitic mites infesting the beetles. This fact, I think, suggests a line of investigation which may lead to a more satisfactory explanation of the association between Chelifers and flies than that put forward in Prof. Hickson's letter.

Zoological Gardens, October 14. R. I. POCOCK.

Incandescence of Meteors.

IT is with great diffidence that I approach this difficult subject, but the theory that the incandescence of meteors is due to the heat generated by the friction between these bodies and the molecules of gas composing our atmosphere I have always found difficult to believe. The following theory is one which has occurred to me, and seems quite a plausible one. Meteors are usually of a metalliferous nature, and consequently will have a comparatively low electrical resistance. When they approach the earth they will enter a magnetic field, and they will cut the lines of force of this field at a high velocity. A high electrical potential will be generated, and consequently electric currents which will be inversely proportional to the resistance. The electrical energy thus produced will be dissipated in heat, and if of sufficient intensity will raise the meteor to incandescence. The truth or otherwise of this theory could, I believe, be calculated, as the data necessary for doing so will be at the disposal of readers of NATURE who make this branch of astronomy their study. This theory may have already been advanced, as I am not in touch with the latest developments of the science.

Coatbridge, September 5. GEORGE A. BROWN.

THE electric currents which the author of the above letter regards as possibly constituting an efficient source of the luminosity of meteors must no doubt arise, and play a certain part in the heat and light development. But the measure in which they can be supposed to contribute to it must clearly be extremely small; or rather, it must be incomparably subordinate to the intense ignition of the air produced, not at all by friction,[1] but by the air's adiabatic compression against the front surface of the meteorite; which is certainly quite competent, by itself alone, to develop what may be said to approach pretty nearly to fabulous degrees of temperature. If the kinetic energy of translation, in foot-pounds ($v^2/2g$), of 1 lb. of the air propelled (at, say, 30 miles per second) with the meteor's speed (v feet/sec.) on its front face, be divided by 330, the number thus obtained (1,180,620° C., in the case supposed) will be the number of centigrade degrees through which it will be heated by the pure process of compression, supposing that the air can continue to subsist at all with its ordinary mechanical deportment and thermodynamical properties unaffected at that enormously high temperature. In the further forward, gradually advancing layers, and in the laterally escaping currents of the air, on which the high forward speed of the meteor is only partially impressed, and which move more slowly on their various courses, the compressions are correspondingly less, and the lower but still exceedingly high temperatures can be similarly calculated from any fair estimates of the air's collective or absolute velocity of translation in those different positions.

It is in the different rates of transport of these heated air-streams, all of them, as well as the highly attenuated motionless atmosphere around, affording very easy passage-ways to electricity, across the earth's magnetic field or system of lines of magnetic force, that fitting circuits can certainly be found (either passing through, or else entirely omitting the meteorite itself), in which, in the way suggested in the above letter, electric currents may be quite certainly concluded to be magneto-electrically induced. For while one part of a closed air-circuit resting against the meteorite's front surface, and another part of it situated in the still atmosphere in front of or behind it, would be journeying towards or from each other with full meteor-speed, the circuits so composed would be most suitably conditioned for developing induced currents round them by

[1] Although a very general belief, it is as yet an entirely mistaken supposition that the high speed of impact of a meteorite into the rarer regions of the atmosphere reduces the air, by giving it no time to dissipate itself in front of the meteorite, to a state of granulation, or to a wedged throng of molecules producing heat by friction *inter se* and against the surface of the meteorite. Just the reverse of this condition is, however, really true, that the air remains a perfectly and frictionlessly elastic fluid, however much it is compressed and intensely heated by the impact. The speeds of sound-waves in the heated air which perform the office of transmitting and maintaining the orderly array of pressures in the streaming flows, at length differ in defect, in fact, from the air's speeds themselves in proportions which, as those mount up to meteor-speeds of many miles per second, only decline asymptotically to about the ratio $1:\sqrt{5}$, or nearly $1:2\frac{1}{4}$. Since, then, these sound-waves, which convey the strokes and shocks of the collision to and fro between the meteor-centre and the surrounding air, arise and travel in the moving field of the compressed air as if it were at rest, it is easy to perceive that by their extremely rapid actions a most exceptionally perfect elastic-fluid relation, or steady disposition of the lines, or lanes of air-flow and blast-pressure, must really be established and maintained in evenly persistent shapes and contour, in the swirl of incandescent air which forms the meteor's head.

their quickly altering enclosures of a constantly changing number of the earth's lines of magnetic force, while thus rapidly opening out or closing up. But the very short extent, not probably much exceeding some few feet or yards, which the swiftest moving part of such a circuit, in meteor-nuclei of various sizes, would embrace, and again the oft-proved weakness of the earth's magnetic field for exciting such induced electric currents, scarcely allow us to expect that any very high voltages would be attained in even the most select cases and the most favourable choices of conditions of such meteoritically produced air-circuits. The hottest, and therefore also probably the best conducting portion of each current's path, compressed against the meteorite's front surface, would also not, presumably, be that in which the heat and light producing action of the current would be strongest, since this would rather be used up in producing brush and glow discharges through the more resisting portion of the circuit in the outer air. The interior parts themselves of stony meteorites, when they have fallen, have not been found, by either sight or touch, to furnish any proofs of having been much heated, but intense effects of heat and fusion on the outer surfaces of fallen meteorites are always very obvious.

While nothing seems to point to any very easily discernible actions of electric currents immediately around a meteor's head, unless we may ascribe to electric agency the occasional production of an "aura" of sparks, or of a misty envelope of light enshrouding it, the stream of heated dust and vapours which travel in a meteor's wake, extending to considerable widths and lengths, as may be often noted, is perhaps a more visibly displayed, and a more evidently and distinctly active scene of luminous discharges of induced electric currents: for the accumulated flow behind the meteor-head resembles in some degree a columnar, vaporous follower of the meteorite itself, left to pursue its course along the meteor-track when the nucleus has disappeared. Being thus virtually a shooting-star of a long-extended shape, but of too dwarfed velocity to raise itself by heat to incandescence, the same induced electric currents as were above inferred to be developed in the meteor's head would here continue to evince themselves along the column by glow discharges in the vapours and the outer air, so long as sufficiently swift flow of the vapours can be persistently maintained through the retarding resistances of the opposing atmosphere. Thus a fairly intelligible *raison d'être* by electric current interventions may not impossibly have been incidentally divulged, by means of the recourse proposed by Mr. Brown to magneto-electric actions, of the long-enduring light-streaks left along the paths of all the swifter class of shooting-stars and larger meteors; the real *modus operandi* of those streaks having always presented to meteor observers a mysterious question for discussion, never admitting hitherto of satisfactory solution by known experimental illustrations, or of any quite surely sound elucidation by less trustworthy conjectures.

A. S. H.

A Rare Game Bird.

I THINK it is worth recording that on Thursday, October 5, Sub-Lieut. H. R. Sawbridge, R.N., shot a quail, *Perdix coturnix*, on Lopham Fen, close to the rising of the waters, the common source of the Waveney and the Ouse, near Diss, Norfolk.

The bird, either a hen or a young male, was very fat—a beautiful little specimen.

The last quail known (by me) to have been shot in this neighbourhood was in the 'fifties of the last century, by Mr. Henry Button, of this parish.

I understand that this bird was much more frequently found in the middle of last century in the neighbourhood of Great Yarmouth, and that, as a rule, it was found singly, as this was, in the autumn.

It is being preserved by Mr. Cole, of Norwich. What was a little foreign bird like this doing singly and alone on our eastern counties' heaths and fens?

Is it a case of lost or strayed, or what is it?

It would be interesting to know whether other specimens of the quail have been heard of inland in the eastern counties of late years.

JOHN S. SAWBRIDGE.

Thelnetham Rectory, Diss, Norfolk, October 16.

PHYSICAL LABORATORIES IN GERMANY.[1]

THE Director-General of Education in India has just published a valuable work in a report by Prof. Küchler, of the Presidency College, Calcutta, on physical laboratories in Germany. It forms one of a number to be included in a volume of the series of occasional reports.

Prof. Küchler "was placed on special duty to inquire into (1) the methods adopted at the universities and polytechnics of Berlin, Munich, Vienna, and other prominent universities and technical institutions in Germany with regard both to the ordinary study of physical science and to the character of the investigations and the system pursued in the case of students who are entering upon a course of independent research. (2) The construction and equipment of modern German laboratories, the special merits of scientific instruments of German manufacture, and the facilities for standardising these instruments which are offered at central institutions in Germany."

In the course of his tour, lasting more than six weeks, the principal universities and technical schools were visited, and the report sums up the information in a useful manner. It is naturally divided into two sections corresponding to the two parts of the reference; the first deals with the methods of study, the second treats of the construction, methods of equipment, &c., of the laboratories. The training of the university undergraduate of necessity differs from that of the pupil of the high school, and both methods are described at some length. Attention is directed to the importance of the set lecture in the scheme of education; the number of lectures given during the session in a university such as Berlin is very considerable, and each lecturer has the use of a properly equipped lecture-room and apparatus. The importance of the organised teaching of practical physics, for medical students, chemists, and engineers, in addition to the professed physicist, is now realised in Germany, and in an appendix, which, however, is not printed in the report, details of the practical instruction at some of the universities and technical colleges are given. In view of the large number of students in some of the German universities, the numbers attending practical classes, as given on p. 7, seem small. At Berlin there are 140 students in two divisions, each under three assistants. The average number of students in the charge of a single assistant comes to twenty-two or twenty-three, which is probably about the same as in one of our well organised English courses.

Students who propose to take a degree in physics work usually for two years at a dissertation. Prof. Küchler specially directs attention to the fact "that students are discouraged from commencing the final stages of their labours before they have been thoroughly trained in practical manipulation and have carefully gone through a complete course of laboratory work such as is represented, say, by Kohlrausch's very elaborate handbook." This fact is sometimes conveniently forgotten by those who urge the adoption of the introduction of research work at an earlier stage in our English training; the average number of these research students is said to be five or six, though, of course, at Berlin, as indeed at Cambridge, the number is much larger.

To illustrate the construction and equipment of the laboratories, Prof. Küchler has given in full the plans of a number of representative institutions, and these plans form a most valuable part of the report. They will enable a professor building or organising a

[1] A Report to the Director-General of Education in India by Prof. G. W. Küchler.

laboratory in India to see readily the arrangements which have commended themselves in Germany, and the report directs attention to the modifications which will be needed to adapt them to Indian conditions.

Perhaps the details which strike an English student most are the number and size of the lecture-rooms, the accommodation provided for the museum, and the absence of rooms specially designed for elementary classes of large numbers.

The Director-General deserves the gratitude of all interested in the organisation of the teaching of physics for having initiated this work, and Prof. Küchler is to be congratulated on the manner he has carried out his task. Still, a companion volume is needed.

British physical laboratories of to-day have many admirable points. A book that described the new laboratories at Liverpool, Manchester, the Royal College of Science, and the McGill University at Montreal, to say nothing of the historic laboratories in our two ancient universities, would contain much to interest those inhabitants of India to whom Prof. Küchler's report appeals, while in many respects, specially, perhaps, in the organisation of the practical work for large classes, the arrangements in the English laboratories seem to have the advantage.

In dealing with the last part of his subject, the construction and standardisation of instruments, Prof. Küchler again rightly directs attention to the important services rendered to German industry by the Reichsanstalt and the disadvantages under which English manufacturers find themselves from the incomplete equipment of the National Physical Laboratory.

THE ESSEX FIELD CLUB.[1]

IN order to mark the completion of a quarter of a century's scientific work in the county of Essex, the above society has published the first issue of a "Yearbook and Calendar" which will be found of interest to all who follow the work of our local scientific societies. This extremely active association was founded in 1880 by Mr. William Cole, the first president being Prof. Meldola. The work of the club has been noticed from time to time in our columns, and the present "Yearbook" contains, as an appropriate opening chapter, a history of the society by Mr. Miller Christy, who is now president. That the club has carried out the objects for which it was founded, and that it has more than justified its existence, is made perfectly clear in this introductory chapter. As the author says, "there is in Essex no other organised scientific body having the same or similar aims."

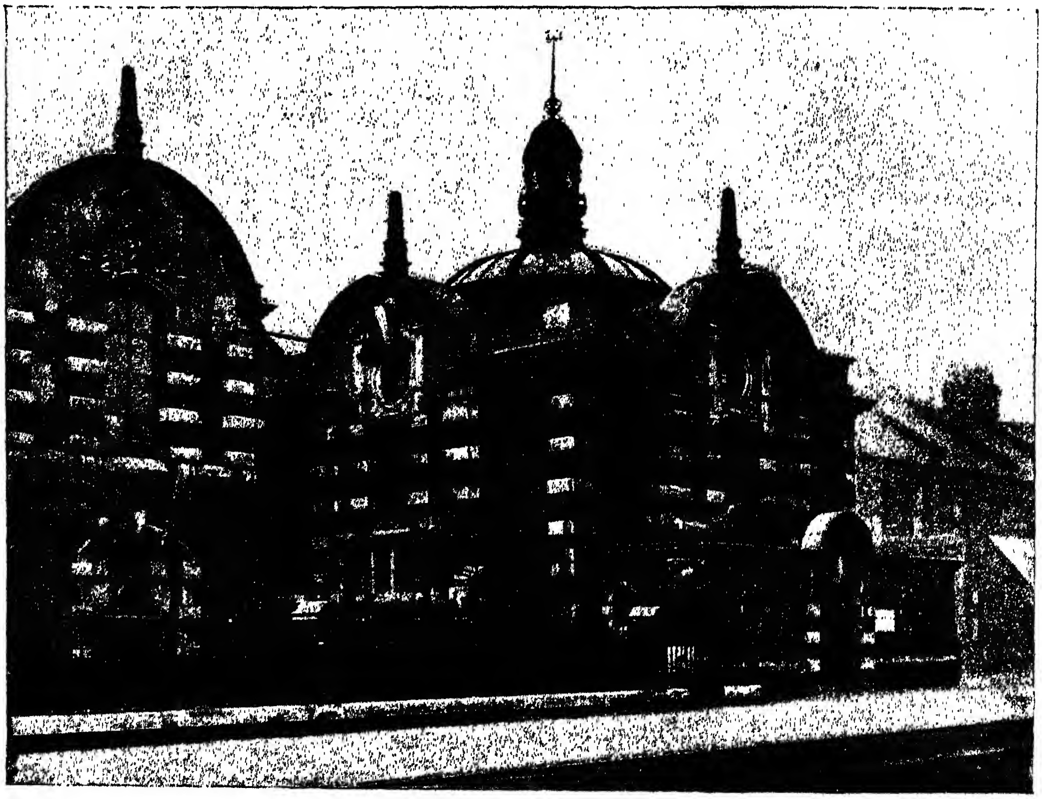

FIG. 1.—The Essex Museum of Natural History, Romford Road, Stratford, Essex.

The actual scientific achievements of the club were fully set forth in an address delivered by Prof. Meldola at the annual meeting in 1901.[2] As regards publications, the output has been not only large in quantity, but, what is more to the point, excellent in quality and strictly appropriate to the functions of a local society. Five volumes of *Transactions and Proceedings* were published down to 1887, after which the official publication was named the *Essex Naturalist*. The fourteenth volume of the latter is

[1] "Yearbook and Calendar for 1905–6." Edited by William Cole. (The Club's Headquarters, and Simpkin, Marshall, Hamilton, Kent and Co., Ltd.) Price 1s.

[2] "The Coming of Age of the Essex Field Club" (1901) Copies can be obtained on application to the Hon. Librarian, Mr. T. W. Reader, Essex Museum, Romford Road, Stratford, Essex.

now in course of publication. In addition to the above periodicals, three "special memoirs" have also been issued, and it is hoped that others will be added from time to time. In 1885 appeared Prof. Meldola's and Mr. White's "Report on the East Anglian Earthquake of 1884," in 1890 Mr. Miller Christy's "Birds of Essex," and in 1898 Mr. Henry Laver's "Mammals, Reptiles and Fishes of Essex." All these works were noticed in our pages at the time of publication. Four "museum handbooks" must also be credited to the club.

Not the least important part of the results achieved since 1880 is the establishment and maintenance of two museums, one of a strictly local character for the Epping Forest district at Queen Elizabeth's Lodge, Chingford, and the other of a county and educational character at West Ham in connection with, and attached to, the Municipal Technical Institute (see illustration). The first of these is carried on under an agreement with the Corporation of London, as conservators of Epping Forest. The other (county) museum was founded for the club by Mr. Passmore Edwards, and is maintained by the Borough Council of West Ham and the Essex Field Club, the library and headquarters of which are now in this same building. The *personnel* of the club as narrated by Mr. Christy is also of interest. The presidency has been held in succession by Prof. Meldola, Prof. Boulger, Mr. T. V. Holmes, Mr. E. A. Fitch, Mr. H. Laver, Mr. F. Chancellor, Mr. David Howard, Prof. Meldola, Mr. F. W. Rudler, and Mr. Miller Christy. All these are still living and active supporters of the club, while Mr. William Cole has acted as hon. secretary, editor of the publications, and curator of the museums during the whole twenty-five years of the society's existence.

There are few, if any, local societies in this country which can show such a good record. The Essex Field Club has earned the gratitude, not only of its own county, but of the world of field naturalists generally for the splendid example which it has set in showing how such organisations can keep alive the spirit of scientific research in the rural districts. In congratulating the club on its past achievements, we feel sure that the wish that its future work may be carried on with equal success will be cordially endorsed by all readers of NATURE.

THE MOSQUITOES OF PARÁ.[1]

IN 1859, when H. W. Bates returned from Pará, the town, though rapidly improving even then, was still a little-known Brazilian port, and Bates embarked on a North American trading vessel, "the United States route being the quickest as well as the pleasantest way of reaching England." At present, however, Pará is a very important place, and well up to date in scientific matters—if we may judge by the handsome publication before us, on one of the more recent branches of scientific inquiry—the transmission of yellow fever and other diseases by means of mosquitoes.

Four essays are included in the present volume, the first dealing with the mosquitoes of Pará regarded as a public calamity. This section is devoted to an historical sketch of the subject, the biology of mosquitoes, the views of various writers on the sanitary importance of the subject, and on the urgent need of practical efforts to abate the evil.

[1] "Memorias do Museu Goeldi (Museu Paraense) de Historia Natural e Ethnographia." IV. Os Mosquitos no Pará. Reunião de quatro trabalhos sobre os Mosquitos indigenas, principalmente as especies que molestam o homem. By Prof. Dr. Emilio Augusto Goeldi. With 100 figures in text and 5 chromo-lithographic plates. Pp. 154. (Pará, Brazil: C. Wiegandt, 1905.)

The second essay contains an abstract of the results of experiments undertaken in 1903, with special reference to *Stegomyia fasciata* and *Culex fatigans*, regarded from a sanitary point of view.

The third essay is devoted to biological details chiefly relating to the development of the principal indigenous species.

The fourth essay consists of a report on *Stegomyia*

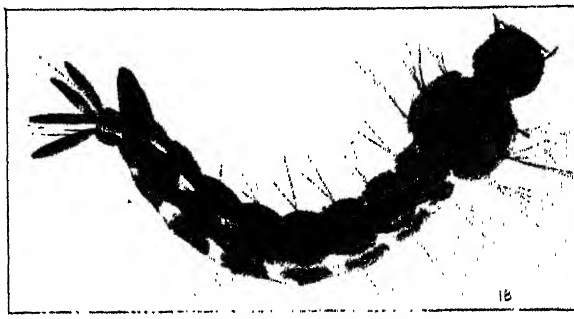

FIG. 1.—Larva of *Stegomyia fasciata*.

fasciata and its connection with the transmission of yellow fever. This was presented to the International Zoological Congress at Berne in August, 1904.

The book appears to be an extremely careful and valuable piece of work, and the paper, printing, and illustrations leave little or nothing to be desired. It must not be overlooked by any worker who is interested in mosquitoes either from a scientific or

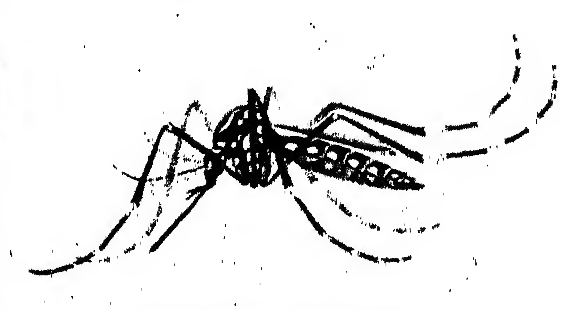

FIG. 2.—*Stegomyia fasciata* ♀ at rest.

from a medical point of view. Several new forms are described; and on p. 73 even the musical note of *Stegomyia fasciata* is discussed—a slight but significant illustration of the intimate connection and interdependence of all branches of human knowledge.

The figures which we have selected for reproduction represent the larva and imago of *Stegomyia fasciata*. W. F. K.

NOTES.

IN connection with the Conservatoire des Arts et Métiers, a museum of industrial hygiene will be opened this month at Paris by the President of the Republic.

PRINCE SERGE TROUBETZKOI, Rector of the University of Moscow, and professor of philosophy in that university, died at St. Petersburg on October 12.

THE death is announced of Mr. A. C. Pass, one of the early and most enthusiastic members of the Bristol Naturalists' Society, and for many years president of the geological section of the society.

A VIOLENT shock of earthquake occurred at Monteleone at 3.40 p.m. on October 14. The shock was felt at Messina at 3.42 p.m.; and a shock is reported to have occurred at Reggio di Calabria at 2.45 p.m.

WE learn from the *Times* that the Royal Prussian Aëronautic Observatory, recently completed, was opened on Monday, October 16, at Lindenberg, in the province of Brandenburg, in the presence of the Emperor William and the Prince of Monaco. The Emperor, in a speech, eulogised the many services rendered by the Prince of Monaco to science, and conferred upon him the large golden medal for science.

THE post-graduate college, West London Hospital, was opened on October 12 with an introductory address by Mr. Tweedy, the president of the Royal College of Surgeons, who emphasised the need for post-graduate training in medicine, and suggested that a post-graduate course should be made compulsory after a certain period in a man's career.

MR. WYNDHAM, M.P., was present at the annual conversazione of the Chester Society of National Science and Literature on October 12, and delivered an address. He accompanied Lady Grosvenor, who made a presentation to Mr. Robert Newstead, formerly curator of the Grosvenor Museum and now attached to the Liverpool School of Tropical Medicine. The gift consisted of a life-size carbon portrait of himself and a purse of more than two hundred guineas. Lady Grosvenor also presented the Kingsley medal to Dr. C. Theodore Green.

AN interesting account is given in the *Times* (October 10) of the cancer department and cancer research at the Middlesex Hospital. Since 1792 the hospital has maintained a separate cancer department by an endowment which first came through John Howard from Samuel Whitbread. The cancer wards, which now contain forty-nine beds, combine the functions of an almshouse or asylum with those of a hospital, for, in accordance with the purpose of the original foundation, the stay of patients is not limited. Howard also contemplated new discoveries from the investigation of a large number of patients and from the accumulated records of these.

THE programme of the London Institution for the session 1905–6 includes the following lectures among others:—The origin of the elephant, Prof. E. Ray Lankester, F.R.S.; submarines, Sir W. H. White, K.C.B., F.R.S.; geographical botany interpreted by direct response to the conditions of life, Rev. George Henslow; the Upper Nile, Sir Charles Eliot, K.C.M.G.; variation in man and woman, Prof. Karl Pearson, F.R.S.; our atmosphere and its wonders, Prof. Vivian B. Lewes.

THE Sociological Society has now issued its programme of meetings arranged for the winter session, along with a list of papers to be delivered before its affiliated societies in the universities of Oxford and Manchester. It is noticeable that a new departure has been made by the Sociological Society in the holding of research meetings (at which papers of interest to specialists only will be read and discussed) in addition to its ordinary monthly meetings for the reading and discussion of papers of general interest. The following papers have been arranged for the ordinary monthly meetings:—The biological foundations of sociology, Dr. Archdall Reid; the origin and function of religion, Mr. A. E. Crawley; and the Institut de Sociologie, its equipment and work, M. Waxweiler. The papers to be delivered at the research meetings are:—The study of the individual, Dr. J. L. Tayler; and biological methods in application to social problems, M. Waxweiler.

AN address of considerable importance from the standpoint of the connection between scientific training and industrial development was recently delivered by Mr. W. Burton on the occasion of the prize distribution to students of the county pottery classes at Tunstall, Staffordshire. At the outset Mr. Burton emphasised the fact that manufacturers in Staffordshire are beginning to realise the value of technical schools as a means of training students to be of real service to them. But, looking backwards, few industries in this country have during the past thirty years drawn so little aid from the resources of science as the pottery industry. The methods employed in pottery at the present day do not differ very greatly from those in use at the time of Josiah Wedgwood. But in science there has been an almost phenomenal advance since the early discoveries of Priestley, the contemporary and friend of Wedgwood. In taking up the study of pottery to-day, the student has to commence for himself almost entirely from the beginning; there is no accumulated store of knowledge and experience, such as exists in all branches of science, from which he may draw. The supreme gift of scientific training in method, Mr. Burton continues, is the power to see. "How many problems are there that present themselves to us every day in our businesses that really disappear—are no longer problems—if we once see them clearly?" The commercial organiser of a business has two problems always facing him, first the economic production of his goods, and secondly the disposal of these goods in the market. A scientific training, in so far as it gives knowledge tending to the solution of these problems, is of direct value to the commercial side of business; many problems can be solved only by scientific methods. But, Mr. Burton urges in conclusion, manufacturers should not look for too immediate results from the employment of a scientifically trained man. "Remember, he must have time to apply his science to your industry. He must have time for experiment, and must be given both leisure and the fullest opportunity to follow out those lines of prolonged and systematic investigation on which alone scientific knowledge has been built."

THE September issue of the *Proceedings of the Philadelphia Academy* contains the first portion of a long paper by Mr. C. S. Sargent on the species of thorns of the genus Cratægus found in eastern Pennsylvania, mainly based on collections and notes made by several local botanists.

THE *Irish Naturalist* for October opens with an illustrated paper by that enthusiastic ornithologist Mr. E. Williams on the recent occurrence in Ireland of a number of specimens of the Greenland and Iceland falcons, more especially the former. Previous records of the occurrence in Ireland of the Greenland falcon included nineteen instances, now raised to twenty-eight by the occurrence of no less than nine examples during the present year. On the other hand, only two previous records of the occurrence of the Iceland falcon were known, this number being raised to three by the capture of an immature female in Galway in March. The author speculates why the Iceland falcon should be so much more rare in Ireland than the far more distant Greenland species.

THE *Halifax Courier* of September 30 contains a full report of a long paper, read at the first meeting for the present session of the Halifax Scientific Society, on the educational value of the Bankfield Museum, by Mr. L.

Roth, the hon. curator. This institution, which is under the control of the Halifax municipality, is devoted to art, local history, numismatics, and ethnology, and it has been the object of the present curator during his whole term of office to make these collections thoroughly representative and of real educational value. Consequently he has rigorously excluded from the exhibition cases all specimens coming merely under the designation of "curios," and devoid of special local or educational interest—an example which might, by the way, be followed by the authorities of at least one rate-supported local museum we could name. Whether this rigid censorship has aroused ill-feeling we cannot say, but at the conclusion of his address Mr. Roth referred in somewhat bitter terms to the apathy displayed by the municipal authorities towards his efforts. Certainly thirty-six guineas a year is not a lavish sum for the needs of such a museum, and the committee appear to have funds at their disposal which they refuse to spend.

No. 13 B. of the *Publications de Circonstance*, recently issued in Copenhagen by the International Council for the Study of the Sea, contains an account of the present condition of the German fisheries in the Baltic, and is a continuation of the publication already issued (No. 13 A) on the Danish and Swedish fisheries in that sea. The present work has been prepared for the German Sea-Fisheries Association by Dr. E. Fischer in cooperation with Prof. H. Henking. It gives in a concise form information as to the different kinds of fishing practised in the area, as well as an account of the boats, nets, and other fishing gear employed, and of the quantities and values of the fish landed. The fluctuations of the various fisheries from year to year for the last ten years are shown in a series of tables and curves, and a number of lithographed charts illustrate the relative local abundance of different species of fish along the German coasts of the Baltic.

THE second part of the first volume of the useful little flora of the upper Gangetic plain, by Mr. J. F. Duthie, has been published recently; it includes the orders Caprifoliaceæ to Campanulaceæ, and the index to the volume.

THE late Prof. L. Errera showed a marked preference for physiological problems, and one of his last papers, which is published in vol. xlii. of the *Bulletin de la Société royale de botanique de Belge*, takes up the difficult subject of the ultimate cause behind reaction in plants. The paper deals with dominance and inhibitory action, as exemplified in the correlation existing between the directions assumed by the main vertical shoot of a tree and its branches under the influence of geotropic stimulus. Nutrition or polarity has generally been invoked to furnish an explanation, but Prof. Errera argues in favour of inhibiting action, possibly due to internal secretions.

REPORTS for 1904–5 on the botanic stations at Antigua and St. Kitts have been received. Owing to the want of uniformity in the amount of *fuzz* on the cotton seed imported from the Sea Islands into Antigua, some doubt was expressed as to its purity. To test the matter some of the seed was graded, and each grade was sown on a separate plot; however, on reaping the cotton, the lint from the different plots did not present any marked difference, and the seed was no more uniform than before. The conclusion is drawn that the character of the lint is fixed, and does not alter with variations in the character of the seed. In St. Kitts and Nevis interest attaches to the cacao and rubber plantations which have been recently started; the rubber plants consist of Castilloa and Funtumia. The work at the agricultural school in St. Kitts is worthy of mention; the practical course includes the cultivation of vegetables, the application of manures to pine and cotton crops, and the propagation of plants by budding and cuttings.

WE have received from the Minister of the Interior the twenty-fourth Bulletin issued by the Peruvian Corps of Mining Engineers. It contains the mineral statistics of Peru for 1904. The production in that year included 59,920 tons of coal, 38,683 tons of petroleum, 2209 tons of lead, 9503 tons of copper, 2675 tons of borates, 18,544 tons of rock salt, 21 tons of sulphur, 145,165 kilograms of silver, and 601 kilograms of gold. Compared with the production in the previous year, noteworthy increases are shown.

THE interesting paper on some phenomena of permanent deformation in metals read by Mr. G. H. Gulliver, of Edinburgh University, before the Institution of Mechanical Engineers in February has now been published in pamphlet form. In making a tension test of a metal bar as soon as the yield-point is reached, the deformation becomes visible to the naked eye as the well known Lüder's lines. Hitherto the lines occurring at the yield-point have been confused with the two straight depressions known as the "contractile cross." The author shows that the two phenomena are quite distinct. In his experiments flat steel bars were used $\frac{1}{8}$ inch in thickness and of various widths from $\frac{1}{2}$ inch to 4 inches.

THE second part of the mines and quarries general report for 1904 has been issued by the Home Office. It contains statistics of the persons employed and of the accidents that occurred. The total number of persons employed at mines and quarries in the United Kingdom and in the Isle of Man in 1904 was 974,634, of whom 877,057 were employed at mines. The death rate from accidents was 1·243 per 1000 persons employed at mines and 1·15 per 1000 at quarries. By the Act of 1903, the value of scientific training in mining is now shown to be appreciated by the Government, the holders of diplomas at institutions approved by the Secretary of State for the Home Department being eligible for managers' certificates after three years' practical experience instead of five as was formerly the case. The list of institutions that have been approved is given in the report, and comprises the Royal School of Mines, the universities of Birmingham, Cambridge, Durham, Glasgow, Leeds, London, Oxford, Sheffield and Wales, the University College, Bristol, the Glasgow Technical College, and the Wigan Mining College.

IN the *American Journal of Science* (vol. xx., No. 118) Mr. Bertram B. Boltwood quotes a number of analyses of minerals containing uranium and thorium, and interprets them by assuming that the ultimate disintegration products of the radio-active elements may include lead, barium, bismuth, the rare earths, argon, and hydrogen. The question is raised whether the quantities of these elements actually existing in nature have not been produced wholly by some such process of disintegration.

IN the *Atti dei Lincei* (vol. xiv. p. 188) B. Gosio describes how the decomposition of exceedingly dilute solutions of alkaline selenites, or, better, of alkaline tellurites, may be utilised as a delicate test for living bacterial contamination. Most living bacteria are capable of decomposing potassium tellurite with the production of a blackish precipitate, becoming themselves, when viewed under the microscope, tinged blackish grey. Dead bac-

teria or spores not undergoing actual development are totally without action on a solution of the tellurite. The test seems to be especially useful for ensuring sterility in the case of liquids or therapeutic sera destined for hypodermic injection.

THE many thermoelectric methods which have been devised during the past few years for the measurement of very high and of very low temperatures have proved themselves of a wide and general utility. But hitherto no instrument of a similar type has been made available for the accurate measurement of temperatures between 0° C. and 200° C. In the *Physical Review* (vol. xxi. p. 65) Mr. A. de Forest Palmer describes a thermojunction consisting of a soft iron wire in conjunction with an "advance" wire containing copper, nickel, and iron, by means of which temperatures within the extremes named may be determined with an error not exceeding 0·04 per cent. Such an instrument is easily calibrated, and in certain circumstances can profitably replace a mercury thermometer of a corresponding degree of accuracy.

Le Radium for September (2e année, No. 9) contains articles on the influence of the connections on the action of vacuum tubes, by M. Charbonneau, on the treatment of cancer with radium, by M. Darier, and a summary of current work connected with radio-activity.

THE *Journal of the Royal Sanitary Institute* for October (xxvi., No. 9) contains articles on the administration of the Food and Drugs Act, by Mr. Wellesley Harris, on the waste of infant life, by Dr. Nash, on hygiene in education, by Mr. White Wallis, and notes on common parasites found in bodies of animals used for food, by Mr. King.

WE have received "Contributions from the Research Laboratory and Sewage Experimental Station," Massachusetts Institute of Technology, Boston, vol. i., 1905. It contains several valuable papers, *e.g.* the mode of action of the contact filter in sewage purification, by Messrs. Phelps and Farrell, determination of organic nitrogen in sewage by the Kjeldahl process, by Mr. Phelps, a study of the methods in current use for the determination of free and albumenoid ammonia in sewage, by Mr. Phelps, and determination of the number of bacteria in sewage, &c., by Mr. Winslow.

MESSRS. F. VIEWEG AND SON, Brunswick, have published a fourth edition of "Hauptsätze der Differential- und Integral-rechnung," by Prof. R. Fricke.

MR. W. B. CLIVE has published a third edition of Dr. G. H. Bailey's "Second Stage Inorganic Chemistry (Theoretical)." This edition has been re-written and enlarged.

THE third, revised edition of "Leitfaden für das zoologische Praktikum," by Prof. W. Kükenthal, has been published by Mr. Gustav Fischer, Jena. The second edition of this work was reviewed in NATURE of April 24, 1902 (vol. lxv. p. 581).

THE first part of a work on "Die ätherischen Öle," by Dr. F. W. Semmler, has just been received from the publishers, Messrs. Veit and Co., Leipzig. It is proposed to issue the work in twelve parts which will make up three volumes, to be completed during next year. The work will be noticed when the whole of the parts have been received.

A THIRD edition of Mr. Tyson Sewell's "Elements of Electrical Engineering" has been published by Messrs. Crosby Lockwood and Son. The book was reviewed in NATURE of November 20, 1902 (vol. lxvii. p. 53), and it is only necessary to mention that more examples have been added to the appendix, and that particulars of the "Wright" and other electrolytic meters have been inserted.

A SECOND edition of Mr. J. W. Russell's "Elementary Treatise on Pure Geometry" has been published by the Clarendon Press. The first edition of the book was noticed in our issue of June 1, 1893 (vol. xlviii. p. 101). Besides numerous small improvements throughout, other changes have been made in the revised edition, and among these may be mentioned the re-arrangement of the examples and the omission of redundant ones. Each chapter has been made independent of following chapters; more use has been made of projection in proofs of theorems, and correlative theorems have been proved by reciprocation. An index has been added.

MESSRS. FLATTERS AND GARNETT, LTD., Deansgate, Manchester, have sent us a specimen of new storage cabinets made by them for lantern slides. Each drawer of the cabinet will hold 100 slides in five divisions, and is fitted with brass handle and space for movable card label. Single drawers are supplied, and cabinets are made with four, six, twelve, and twenty-four drawers. There are no grooves in the drawers, but the top edges are cut down a little, so that the slides rise above the edges and can readily be lifted out. The cabinets provide a convenient and neat means of storing lantern slides. A despatch box also submitted by Messrs. Flatters and Garnett is fitted at each end with a strip of brass which clasps the cover when the slides are in transit, and can be swung off immediately the slides are required. This box has the usual rubber packing to prevent shock and breakage.

OUR ASTRONOMICAL COLUMN.

ANOTHER LARGE SUN-SPOT.—Another large group of sunspots, the fourth or fifth this year to be visible to the protected naked-eye, is now to be seen on the solar disc not very far from the centre. The group, which consists of a large number of separate small nuclei, is, roughly, 100,000 miles across its longest diameter, and was first seen coming round the limb on Saturday, October 14.

M. BIGOURDAN'S ECLIPSE RESULTS.—M. Bigourdan, who was placed in charge of the Bureau des Longitudes expedition to Sfax (Tunis) to observe the recent total eclipse of the sun, communicated the preliminary results of his observations to a meeting of the Paris Academy of Sciences held on October 2. The greater part of his communication consisted of descriptions of the instruments employed and the conditions they were employed under.

A coronagraph, designed to take numerous large-scale photographs, in order to show the relation between the details of the inner corona and those on the corresponding regions of the solar disc, became deranged after the second plate was exposed, but the two plates obtained show numerous details of the inner corona. In a second coronagraph, of 0·95 m. focal length and 0·15 m. aperture, a green glass screen, transmitting only those wave-lengths near to λ 530, was placed in front of the plate, and the exposure made to last throughout totality. The negative obtained shows the corona extending for about 30′ from the moon's limb.

Two spectroscopes having slits much longer than the diameter of the solar image were employed, the slits being so arranged that the spectrum of the coronal radiations at points situated at the ends of the sun's axis and equator respectively might be photographed. Photometric observations of the corona, both visual and photographic, were also made.

Observations of the terrestrial magnetic elements showed that the variations caused by the interposition of the moon were but small. The shadow bands formed a very striking

feature of this eclipse, and were recorded by many observers at Sfax as being sinuous, undulating, and nearly parallel. They travelled at a rate equal to the average walking pace of a man (*Comptes rendus*, No. 14).

ATMOSPHERIC ORIGIN OF "SHADOW BANDS."—In No. 4049 of the *Astronomische Nachrichten* Signor T. Zona, of Palermo, suggests that the shadow bands observed during a total eclipse of the sun are of a purely atmospheric origin. He has observed that the rays of light projected from a man-of-war's searchlight on to a wall several kilometres from the ship exhibit just the same kind of light and dark bands that he observed at Sfax during the recent solar eclipse.

Similarly, he noticed that the light from Venus projected through a small window on to the opposite wall of the room in which he was seated exhibited the same appearance.

Signor Zona suggests that the atmospheric vibrations which cause the agitation seen at the sun's limb, when the latter is observed directly, are the cause of the oscillating bands seen during total eclipses.

A SPECTROGRAPHIC DETERMINATION OF THE SOLAR PARALLAX.—In Nos. 4048–9 of the *Astronomische Nachrichten* Herr F. Küstner describes in detail a method which he has employed to determine the sun's parallax spectrographically, from measurements of sixteen lines on each of eighteen spectrograms of Arcturus, obtained during the period June 24, 1904–January 15, 1905, with the Bonn spectrograph. From these measurements he found the radial velocity of Arcturus relative to the sun to be -4.83 ± 0.27 km. for the epoch 1904·8, and the value for the mean velocity of the earth to be 29.617 ± 0.057 km., the accepted value for the velocity of light *in vacuo* being 299865 ± 26 km. per second.

As the solar parallax previously accepted, viz. 8″·800, is based on the assumption that the earth's velocity is 29·765 km., and as these two quantities vary proportionally, it follows that with a more correct value for the latter a more refined value for the former may be determined.

Having made the determination, Herr Küstner arrives at the quantity $8''.844 \pm 0''.017$ as his final result for the value of the solar parallax.

NOVA AQUILÆ NO. 2.—The results of several recent observations of the Fleming Nova are published in No. 4049 of the *Astronomische Nachrichten*.

Prof. Wolf, observing on September 17 at 8h. 4·3m. (Konigstühl M.T.), found the Nova's magnitude to be 9·6, showing a decrease of not quite 0·3 mag. since September 4.

Dr. Guthnick, observing at Bothkamp, obtained the photometric results shown in the following table:—

1905	M.T. Berlin	Mag.	1905	M.T. Berlin	Mag.
Sept. 5	8 9h.	10·32	Sept. 14	8·3h.	10·47
,, 8	10·3h.	10·30	,, 19	9·2h.	10·55
,, 12	10·1h.	10·40	,, 22	9·3h.	10·66
,, 13	9 0h	10·52	,, 23	9·1h.	10·63

The magnitudes are based on those given for the comparison stars in the Harvard photometric revision of the B.D. catalogue.

LIGHT-VARIATION OF SATURN'S SATELLITES.—From observations made on twelve evenings, Dr. P. Guthnick, of Bothkamp Observatory, has determined the phases of the magnitude changes of Tethys, Dione, Rhea, and Titan.

He found that the first named is brightest when at easterly elongation (90°) and faintest at about 330°. Dione reaches its maximum brightness at 90° and its minimum at about 40°. Rhea apparently has two maxima, one at 40°–120° and a fainter one at 240°, the corresponding minima occurring at 180° and 330° respectively. The maximum brightness of Titan occurs at 240°, its minimum brightness at 20°. In regard to Japetus, Dr. Guthnick's observations confirm the results obtained by Prof. Pickering, viz. that the maximum brightness of that satellite occurs at the western, and the minimum at the eastern, elongation. The range of light-variation for each of the satellites Tethys, Dione, and Titan is about 0·75 mag., for Rhea about 1·0 mag., and for Japetus about 1·75 mag. (*Astronomische Nachrichten*, No. 4049).

INTERNATIONAL CONGRESS ON RADIOLOGY AND IONISATION.

THE first international congress for the study of radiology and ionisation, organised under the auspices of the Belgian Government, was held at Liége on September 12–14. The work of the congress was divided into two sections, devoted respectively to physical and biological science. The first section dealt with the following questions:—(1) physics of electrons, comprising also radiations of all kinds; (2) radio-activity and the accompanying transformations; (3) meteorological and astronomical phenomena attributable to ionisation, radio-activity, and to radiations of different kinds. The second section had for its scope the study of the physiological properties of the radiations and their application in medicine.

The opening session of the congress was held in the physics theatre of the University of Liége on September 12, under the presidency of Prof. Kuborn, member of the Royal Belgian Academy of Medicine. Among the members present may be named Profs. Becquerel, Bouchard, and Bergonié, representing the French Republic, Señor J. Muñoz del Castillo, officially representing Spain, Drs. E. F. Nichols and W. Dieffenbach (United States), Prof. Hurmuzescu (Roumania), Prof. Gillon (Italy), Dr. Yankorits (Servia), Lion Sy Thang (China), Dr. Arrago (Guatemala), Dr. Ortiz (Argentine). Prof. Lassar represented the Röntgen Association of Berlin, Prof. Onnen the Royal Society of Batavia, and Mr. Wilton the University of Adelaide, South Australia. The following were also present:—Messrs. Birkeland, Himstedt (Freiburg in B.), Gariel (Paris), and Legge (London).

Sir William Ramsay had intended to present an address on radio-thorium, but in his unavoidable absence it was read on his behalf. M. Becquerel gave a lecture on the analysis of the radiations of radio-active substances. The address will be published in the *Comptes rendus* of the congress, shortly to be issued by the organising committee (general offices, No. 1 Rue de la Prévôté, Brussels).

On September 13 a general meeting was held. Prof. Wind, of Utrecht, presented a communication on the diffraction and wave-length of the *n*-rays, and demonstrated the character of the apparatus designed by his colleague M. Haga and himself for the study of this much controverted question. Prof. Lassar, of Berlin, gave an account of the practical application of the new radiations. M. Tommasina, of Geneva, described a study of the radio-activity produced by atmospheric air (Elster and Geitel's phenomenon), and papers relating to the therapeutic action of the X-rays and of radium were read by Drs. Bergonié (Bordeaux), Dieffenbach (New York), and Kassabian (Philadelphia). The latter's hands, owing to their frequent exposure to the radiations used for therapeutic treatment, have during the past few years undergone characteristic changes.

The following papers of noteworthy interest were presented at later meetings:—Remarks relative to the terminology of ionisation, Prof. de Hemptinne (Louvain); disruptive discharge in gases at high pressures, Prof. Guye (Geneva); the spectroscopic study of radium light, Prof. Himstedt (Freiburg in B.); the kinetic theory of the electron serving as a basis for the electronic theory of radiation, Dr. Tommasina (Geneva); on the radio-active constituents of sediments from Echaillon and Salins-Moutiers, Dr. Blanc (Rome); a new apparatus for determining the radio-activity of spring-waters, Dr. H. Sieveking (Karlsruhe); Moser's radiations, Prof. Piltschikoff (Kharkoff); discharge phenomena caused by X-rays and radium radiations, and the transformation of these rays, Prof. Hurmuzescu; critical observations on the theories of atomic disintegration and chemicophysical dissociation, Prof. Muñoz del Castillo; the method of transmission of excited activity to the kathode, Mr. Makower (Manchester); radio-activity of the lava from Vesuvius (eruption of 1904), Dr. Tommasina; on the change of properties of the chemical elements, Prof. Fabinyi (Kolozsvar, Hungary); (1) the experimental methods of studying the transformations of the X-rays and the secondary rays resulting therefrom, (2) classification and mechanism of the different electric phenomena caused by the X-rays, Prof. Sagnac (Paris); absorption phenomena of radium and polonium

rays, Prof. Riecke (Göttingen), paper presented by Dr. Emil Bose.

Limitations of space prevent the enumeration of papers not read at the congress but accepted for insertion in the *Comptes rendus*, as well as of the communications read before the biological section. The final meeting of the congress was held on September 14. After several interesting communications had been read, including one from Sir William Huggins, presented by Prof. Becquerel, the following motion was put before the meeting by the executive of the congress, acting at the wish of Prof. Jose Muñoz del Castillo:—

The International Congress for the Study of Radiology and Ionisation assembled in plenary session at Liége on September 14, 1905, considers that, although State regulation and protection may sometimes impede free research among men of science, it is, however, necessary that Governments should, without creating monopolies, be brought to apply to radio-active substances the same legislative measures that prevent the monopolisation of other useful substances, and should guarantee by the play of economic laws free scientific research and the application of these substances to the treatment of the sick; and considers also that it is desirable to be able to advise or remind the Governments of the importance of these measures and that a permanent commission invested with powers by the actual congress, an assembly of men of science devoted to the study of these questions and belonging to different countries, would carry weight in discussing with public authorities matters appertaining to the needs of science or the requirements of the sick. It has therefore decided

(1) That an international commission for examining all questions of general interest relative to radio-active substances shall be instituted.

(2) That the commission shall meet regularly each year, and may be convened on any exceptional occasion by the president, acting with the majority of the executive.

(3) That it shall organise periodically international congresses, to meet every five years, and shall also be empowered to convene the congress in extraordinary session.

(4) That the members of this commission shall be subject to re-election at each meeting of the International Congress.

THE COALFIELDS OF NORTH STAFFORDSHIRE.

THE memoir described below[1] contains detailed accounts of the coalfields of North Staffordshire, especially those of the Pottery and Cheadle Coalfields. The re-survey on the 6-inch scale was commenced in 1898 and completed in 1901. The present volume, which contains detailed descriptions furnished by each geologist of the area surveyed by himself, has been largely written and edited by Mr. Gibson, who personally carried out the greater part of the field-work. It was pointed out by Beete Jukes long ago that, so far as the higher portions of the Coal-measures were concerned, North Staffordshire provided the type development of the Midlands. Mr. Gibson has now established in that region a definite stratigraphical sequence in the comparatively barren strata which conformably overlie the productive Coal-measures, and he has also proved that the same sequence may be recognised in the other coalfields of the Midland area.

The chief points of interest are contained in chapter iv., which describes fully the determination of the Newcastle-under-Lyme group, the Etruria Marl group, and the Black Band group, and more particularly the removal of Hull's "Salopian Permian" into the Carboniferous. A full account of the palæontological and stratigraphical evidence on which this change is based is given at pp. 53 to 55. The evidence shows that the Salopian Permian of Staffordshire, Denbighshire, Worcestershire, Warwickshire, and in all probability Lancashire, occurs as the highest group of a definite sequence everywhere overlying the higher beds of the true Coal-measures, but never discordant to them, and that the Salopian Permian on either side of the Pennine Chain conforms to the Coal-measures, but is unconformably overlain on the eastern side by the Magnesian Limestone series.

It has been found advisable to adopt purely descriptive terms for various subdivisions, and for similar reasons the expressions Upper, Middle, and Lower Coal-measures have not been adopted, since the positions of the palæontological boundary lines which give a definite significance to the terms have not been determined with accuracy. Since the memoir was written, Mr. R. Kidston has contributed a paper to the Geological Society on the divisions and correlation of the upper portions of the Coal-measures, in which he proposes the name "Staffordian" for the series included between the Black Band group and the Newcastle-under-Lyme group, while the Keele group and similar beds in the Midland coalfields, hitherto referred to the Permian system, are classed with the Radstock group, previously called Upper Coal-measures. The distribution of the plants certainly favours such a classification, but there is evidence which seems to show a gradual passage of one group into another, and Dr. Hind, who has devoted considerable attention to the study of the lamellibranchs, is not in favour of the proposed subdivision.

One of the most pleasing features is the accurate and complete description of the palæontology, which is treated in detail by Mr. John Ward, and is accompanied by full lists, with six plates, of the common fossils of the Coal-measures. The Pottery Coalfield has long been recognised as an unrivalled field for the study of Carboniferous fishes, the study of which has to some extent overshadowed the examination of a numerous and varied series of molluscan remains and the equally abundant flora it has yielded. In this section Dr. W. Hind has given Mr. Ward a great deal of assistance. The fossil fishes have been named by Dr. Traquair and Dr. Smith Woodward, while the plants have been dealt with by Mr. Kidston. A complete geological bibliography of the North Staffordshire coalfields, covering fifteen pages, forms a valuable appendix.

The Triassic and Glacial deposits are described in separate chapters, and the economic products of the Pottery Coalfields are treated in chapter xii. The latter account includes the consideration of the future coal supply of the district from the concealed coalfield, to which considerable attention is paid. In addition descriptions are added of the local building stones, clays, and marls, supplemented by an enumeration of the chief source of water.

H. W. HUGHES.

1 "Memoirs of the Geological Survey of England and Wales. The North Staffordshire Coalfields." By W. Gibson. With Contributions by G. Barrow, C. B. Wedd, and J. Ward. Pp. vii+494; with 1 Coloured Map and 6 Plates. (London: Edward Stanford, 1905.) Price 6s.

THE DISTRIBUTION OF POWER.[1]

TWENTY-SIX years ago, at the meeting of the British Association at Sheffield, August, 1879, a lecture, on "Electricity as a Motive Power," was delivered to some thousands of working men, and, for the first time, they realised that forks and spoons could not only be plated with the electric current, but could also be polished with a brush made to spin with the same agency.

The sea of upturned faces beamed with delight when Jack, their popular comrade, stepped on to the platform, took the newly plated spoon in his hands, and burnished it —a pair of thin wires tied to a church steeple being the only connecting link between the dynamo machine in a neighbouring works—ordinarily used there for electro-plating—and the electro-motor driving the polishing brush in the Albert Hall, Sheffield.

But an electro-motor is only a toy, thought my audience; nobody could construct an electro-motor that we could not stop with our hands; and at the end of my lecture they actually tried, and—wondered.

As far as I am aware, it was at that lecture that the following composite suggestion was first put forward—to obtain economy in electric transmission of power the current must be kept small, while to transmit much power the electric pressure between the conducting wires must be made large; and, lastly, to secure safety and convenience

1 Lecture delivered on Tuesday, August 29, at a meeting of the British Association in Johannesburg, by Prof. W. E. Ayrton, F.R.S., and illustrated with many experiments on moving machinery, diagrams, and lantern slides, two lanterns being used, in the American fashion, for enabling pictures to be contrasted on the screen.

SUPPLEMENT TO "NATURE."

A TIBETAN DICTIONARY.

A Tibetan-English Dictionary with Sanskrit Synonyms. By Sarat Chandra Das. Revised and edited by G. Sandberg, B.A., and A. W. Heyde. Pp. xxxiv+1353. (Calcutta: Bengal Secretariat Press, 1902.)

THE chief attraction which the Tibetan language possesses for the western reader is that it is the Latin of Central Asia, and preserves in its bulky literature the old-world lore and vestiges of early culture which the priestly schoolmen of Tibet believed to be all that was worth knowing, not only about their own country, but of the outside world, and more especially ancient India, regarding which so little is known to us. For Tibet, upon receiving its Buddhism from India in the seventh century A.D., adopted at the same time the Indian characters for the purpose of reducing its hitherto unwritten Mongolian language into writing, and forthwith translated into its new vernacular the Indian Buddhist scriptures and other works, the originals of which were afterwards destroyed by the fanatical Mohammedan invaders on the expulsion of Buddhism from India in the twelfth century A.D. From these scripts, thus preserved in their Tibetan translations, much invaluable information has already been gleaned by European scholars; but owing to a habit of the learned monks to translate most of the proper names, of persons, places, and things, root by root etymologically into the Tibetan, it so happens that without a copious Tibeto-Sanskrit lexicon to re-convert these translated names into their recognisable Indian equivalents, a great deal of the mass of information locked up in the Tibetan volumes, now accumulating in our national libraries, remains to some extent sealed.

This is what the present dictionary claims to facilitate to a greater extent than has been done by the lexicons of the pioneer Csoma, the Hungarian, the scientifically equipped Moravian missionary, Jäschke, and Père Desgodins. It has been compiled by Babu Sarat Das from vernacular dictionaries brought by him from Tibet, when he visited that country some years ago. His revisers complain that they found "the material had been put together in somewhat heterogeneous fashion hardly systematic enough for a dictionary," so that they had to take "the greatest freedom in correcting or rejecting the matter set forth in the work." This task of correction has obviously not been carried far enough, for in its published form this ponderous volume still retains serious shortcomings in the elementary requirements of a dictionary. The definitions offered are too often wanting in accuracy to be trusted, or too wanting in necessary details and useful references to be very helpful. The Sanskrit synonyms are not so numerous as they might have been, and their definitions are usually made up of indiscriminate extracts from the Sanskrit-English dictionaries of English lexicographers, reproduced often without acknowledgment and with strange confusion and errors.

For instance, to refer to some of the botanical matters in the first few pages, under "Kakola," an aromatic spice, the author has taken the latter part of his definition from Wilson's dictionary without acknowledgment, and included with it part of the definition of the next following word; he also states that cardamom is "the fruit of *Cocculus indicus*," and mistakes Erandi or cubeb pepper for Erand, or the castor-oil plant. Again, "Kapi" is given in trustworthy Tibetan lexicons as the Sanskrit equivalent of "Ka*p*ittha," not "Ka*b*ittha" as stated by the Babu, and secondarily "Pithanaja," which is omitted by him. The primary meaning, therefore, is the wood-apple tree (*Feronia elephantum*) and not "resin of the juniper plant" as given by him. As secondary meanings he inserts five lines taken without acknowledgment from Wilson, and in so doing misspells each of the three botanical names, and alters "waved-leaf fig tree" into the nonsensical "manefig tree." In the next word, also, both the Sanskrit and botanical terms, taken unacknowledged from Wilson, are misspelt.

Again, "Chu-sing kar-po," or "the white water-tree," is absurdly stated by him to be *Aconitum ferox*, which, however, is black rather than white, and never called a "tree" by the Tibetans, to whom it is familiar. The vernacular lexicon, however, gives for "water-tree" the Sanskrit "Kadali," or "water-wood," which is the appropriate name of the watery plantain tree, and it gives the further synonym "Mochaka," or the "horse-radish-tree," which the Babu omits. Of this tree, the "Sajina" of Indian cooks, there are two varieties, namely, a red and a white kind, the latter of which is the one that has been wrongly identified with the deadly aconite by our compiler. Still another synonym for this word, "Nālam," a reed or "stalked water-plant," is incorrectly given as "the ratan" (*sic*); and the author frequently confuses cane with bamboo.

Not infrequently the precise shade of meaning is missed; thus *Rig-dsin*, which literally and invariably means "a holder of knowledge" or sage, is defined by him as "comprehension of a science (*sic*) with ease"; and seldom is any hint given of the useful literal meaning of such names as the common word for small-pox, which is euphemistically called "God's granules" in deference to the malignant disease spirit.

As instances of common words altogether omitted are *La-lis*, the respectful form of "yes," which after the mystic "*Om*" formula is perhaps the word most frequently uttered in Tibet; *Choma*, the common Potentilla, the root of which is eaten as a food; *pin-kyur-ma*, the kestrel, being onomatopœtic for its call; the word for "bribe," which is ethically interesting as meaning literally "a secret push."

His orthography disregards some of the accepted rules of scientific philologists, so as to give "Daipung" for the great monastery of Däpung, although no *i* occurs either in the vernacular spelling or pronunciation. We miss, too, in a dictionary of this size, which owing largely to clumsier type is

thrice the weight of Jäschke's, any illustrations of the interesting process of organic change whereby so many of the bristling consonants of the written speech have dropped out of hearing in the spoken dialects of the temperate central province, probably for physiological and climatic reasons.

Nevertheless, despite its many defects, it embodies a good deal of new material from the vernacular Tibetan lexicons which must prove suggestive to those engaged in Tibetan researches who are sufficiently advanced not to be misled by its serious mistakes.

L. A. WADDELL.

FINGER-PRINT IDENTIFICATION.

Guide to Finger-print Identification. By Henry Faulds, L.F.P.S., late Surgeon Superintendent of Tsukiji Hospital, Tokyo, Japan. Pp. viii+80. (Hanley: Wood, Mitchell and Co., Ltd., 1905.) Price 5*s*. net.

DR. FAULDS was for some years a medical officer in Japan, and a zealous and original investigator of finger-prints. He wrote an interesting letter about them in NATURE, October 28, 1880, dwelling upon the legal purposes to which they might be applied, and he appears to be the first person who published anything, *in print,* on this subject. However, his suggestions of introducing the use of finger-prints fell flat. The reason that they did not attract attention was presumably that he supported them by no convincing proofs of three elementary propositions on which the suitability of finger-prints for legal purposes depends. It was necessary to adduce strong evidence of the, long since vaguely alleged, permanence of those ridges on the bulbs of the fingers that print their distinctive lineations. It was necessary to adduce better evidence than opinions based on mere inspection, of the vast variety in the minute details of those markings, and finally, for purposes of criminal investigation, it was necessary to prove that a large collection could be classified with sufficient precision to enable the officials in charge of it to find out speedily whether a duplicate of any set of prints that might be submitted to them did or did not exist in the collection. Dr. Faulds had no part in establishing any one of these most important preliminaries.

But though his letter of 1880 was, as above mentioned, apparently the first *printed* communication on the subject, it appeared years after the first public and *official use* of finger-prints had been made by Sir William Herschel in India, to whom the credit of originality that Dr. Faulds desires to monopolise is far more justly due. Those who care to learn the facts at first hand should turn to NATURE, vol. xxii. p. 605, for Dr. Faulds's first letter, to vol. l., p. 518, for a second letter from him in reference to the Parliamentary Blue-book on the "Identification of Criminals," then just issued, and lastly to Sir Wm. Herschel's reply in vol. li., pp. 77–8, where the question of priority of dates is placed beyond doubt, by the reprint of the office copy of Sir William's "demi-official" letter of August 15, 1877, to the then Inspector of Prisons in Bengal. This letter covers all that is important in Dr. Faulds's subsequent communication in 1880, and goes considerably further. The method introduced by Sir Wm. Herschel, tentatively at first as a safeguard against personation, had gradually been developed and tested, both in the jail and in the registering office, during a period of from ten to fifteen years before 1877, as stated in the above quoted letter to the Inspector of Prisons.

The failure of Sir Wm. Herschel's successor, and of others at that time in authority in Bengal, to continue the development of the system so happily begun, is greatly to be deplored, but it can be explained on the same grounds as those mentioned above in connection with Dr. Faulds. The writer of these remarks can testify to the occasional incredulity in the early 'nineties concerning the permanence of the ridges, for it happened to himself while staying at the house of a once distinguished physiologist who was the writer when young of an article on the skin in a first-class encyclopædia, to hear strong objections made to that opinion. His theoretical grounds were that the glands, the ducts of which pierce the ridges, would multiply with the growth of the hand, and it was not until the hands of the physiologist's own children had been examined by him through a lens, that he could be convinced that the lineations on a child's hand might be the same as when he grew up, but on a smaller scale.

The literature concerning finger-prints is becoming large. An excellent index to it will be found in a memoir by Otto Schlaginhaufen, just published (*Morphol. Jahrbuch,* Bd. xxxiii., H. 4, and Bd. xxxiv., H. 1., Leipzig). But even this is incomplete, for it takes no notice of Mr. Tabor's efforts in San Francisco to obtain the official registration of the finger-prints of the Chinese immigrants, whom it was found difficult to identify otherwise. This seems to have occurred at some time in the 'eighties, possibly before them, but dates are now wanting.

Dr. Faulds in his present volume recapitulates his old grievance with no less bitterness than formerly. He overstates the value of his own work, belittles that of others, and carps at evidence recently given in criminal cases. His book is not only biased and imperfect, but unfortunately it contains nothing new that is of value, so far as the writer of these remarks can judge, and much of what Dr. Faulds seems to consider new has long since been forestalled. It is a pity that he did not avail himself of the opportunity of writing a book up to date, for he can write well, and the photographic illustrations which his publisher has supplied are excellent. The experiences of other countries ought soon to be collated with those of England, in order to develop further the art of classifying large collections of finger-prints. In Argentina, for example, their use has wholly superseded Bertillonage, and one would like to know with what success. A bureau that can deal effectively with very many thousands of cases would require a staff of particularly intelligent officials, and the tradition of dealing in the same way with certain transitional forms that are of frequent occurrence. The more highly the art of

classifying, or as it might be phrased of "lexiconising," finger-prints is developed, the more wide will their use become. They ought to be especially valuable in checking desertions from the Army and Navy. But there may be moral objections to the use of finger-prints in these cases for, according to the present system of recruiting, many take refuge in the Army who are "wanted" by the police, and would strongly object to being finger-printed.

A few words should be added concerning the ancient usage of finger-prints in China, Japan, and India for legal purposes. Good evidence as to this has at length been supplied by Minakata Kumagusu in two letters to NATURE, vol. li., pp. 199 and 274. It is clear that it *was* used to some extent, but there is nothing as yet to show that the impressions were made and scrutinised with anything like the precautions now considered to be essential to the good working of the system. Blurred finger-prints cannot be correctly deciphered except by a trained expert, using lenses and photographic magnification. Negative evidence is often of conspicuous value, such as should leave no reasonable doubt in the mind of the most stupid juryman; but expert analysis and severe cross-examination are required when the prints to be compared are generically alike and when one of them is imperfect or blurred.

F. G.

EDUCATION AND PHYSIQUE.

Mécanisme et Éducation des Mouvements. By Prof. Georges Demeny. Pp. ii + 523; 565 figures. (Paris: Félix Alcan, 1904.) Price 9 francs.

THERE are few more important or more opportune considerations in connection with practical hygiene than those which are furnished by the subject-matter of the two books written by M. Demeny. The first of these books, a second edition of which appeared in 1903, is entitled "Les Bases scientifiques de l'Éducation physique"; this is now supplemented and given a direct practical bearing by the present work, which sets forth in some detail the technical aspects of the subject. As regards its general character the method of treatment remains distinctly scientific; but since the avowed aim of the author is to set forth the real advantages to be derived from bodily exercises conducted along proper lines, the scope of this later book is eminently educational, and thus it appeals to all those who take a broad view of education and its requirements. This appeal is accentuated by the mode of presentation, which is such as to render the extensive subject-matter intelligible to those who make no pretensions to special physiological knowledge.

It is true that the opening chapter deals of necessity with such physiological questions as the structure and functions of muscle, the mechanism of joints, and the capacity for movement which are allowed by the skeletal articulations; but these and other fundamental points of like nature are treated in a manner which, whilst in strict accord with the present state of scientific knowledge, is of such a character as to render these various topics easy of comprehension. This introduction leads up to a most interesting analysis of the part played by the muscles in producing various well known body movements. In this stress is laid upon the comparatively modern discovery that any movement, for instance the flexion of a limb, is produced not only by the pulling force of those muscles which move it in the desired sense, the flexors, but also by the relaxation of those which oppose this movement, the extensors. It is this two-fold muscular mechanism which permits of the movement being graduated so finely as regards both its extent and its force. Some illustrations of a striking character are given in support of this aspect of a volitional or secondary automatic movement.

For the majority of readers, the great interest of the book will probably lie in the interesting account which it gives of various familiar movements. These are all accompanied by numerous illustrations which are excellent for their purpose, and greatly enhance the attractiveness of the text. Many of these are spirited diagrammatic representations of the skeleton, the form of which in all manner of bodily postures is drawn with that piquancy and verve which constitute to English eyes the special charm of French draughtsmanship; humour cannot be expected in a letterpress which deals with subject-matter so technical and serious, but it is supplied by the illustrations, which give a humorous fillip to the work without detracting in the least from their undoubted service in helping the reader to follow the exposition.

The section which deals with the various forms of locomotion, walking, running, jumping, &c., is perhaps the most elaborate. The author is here on ground which he has studied minutely for many years. As chief of the laboratory at the physiological station in the Collège de France, he is able to set forth with authority the results of the elaborate and prolonged investigations initiated by Prof. Marey and carried on under his inspiring influence. It is probable that the summary of these investigations given by M. Demeny is the most valuable short exposition of this really difficult subject which has been published up to the present time. The lucidity of the author's style and treatment is conspicuous in this portion of the book, for the matter dealt with is not easily set forth in a way which admits of being readily understood, since it involves mathematical considerations which are apt to prove a stumbling block to physiological students.

But, as stated before, the description of the factors concerned in the production of familiar postures of the body and the side-issues which these raise, will for most readers probably prove the most attractive portion of the work. From standing, sitting, and lying down, the author proceeds to carrying loads, vaulting, kicking, throwing, swimming, rowing, cycling, horse-riding, dancing, singing, fencing, boxing, wrestling, and all the various bodily movements which are concerned in the various forms of athletic or industrial exercise. It would be impossible to give any detailed account of his treatment of these subjects, but it may be confidently stated that this treatment, whilst scientifically sound, is rendered

entertaining by the copious illustrations and interesting through the many novel points which are touched upon. As an example of the latter, the question is raised as to the physiological limits of the rapidity of effective response in fencing and boxing, and experiments are cited bearing on this point.

A more serious, and at the present moment more important, aspect of the subject-matter is that which deals with body movements in relation to the improvement of general bodily physique. These are dealt with in the same comprehensive manner as those just referred to, for the author includes most of the gymnastic exercises used in France, Swedish drill, the use of clubs and of apparatus of different kinds.

The malformation of the body is also referred to, whether due to the under-development or to the over-development of special muscular groups; as an example of the first, the malformation of the chest through the weakness of the trunk muscles, abdominal muscles, &c., is conspicuously shown; as an example of over-development, the malformation of the thigh in fencing masters.

The closing chapters are devoted to the conditions which may be presumed to determine how muscular force can be most economically directed towards the production of body movements. The author realises that it would be undesirable in a treatise of a semi-popular character to present this extremely important subject in detail; nor, indeed, can it be set forth in a very convincing manner, since several questions of a fundamental type are still from the scientific point of view in an unsettled state. Thus it is still a matter of doubt how closely the heat-producing properties of muscle are associated with those of mechanical tension or change of form. M. Demeny is well aware of this, and warns his readers that it is impossible to deduce the energy relationships of the animal mechanism from those of artificially constructed machines. In this as in other departments of physiology the hope of arriving at a more precise intellectual standpoint is that expressed by one of Bacon's aphorisms; it will "only be well founded when numerous experiments shall be received and collected into natural history which, though of no use in themselves, assist materially in the discovery of causes and axioms."

In this spirit the various experiments detailed in the concluding chapter of the book must be approached. Most of these are concerned with the influence of walking with definite loads for definite distances; the points noted were the number of steps per minute, the length of the stride, and the posture of the body. It appears that when, as in walking, muscular movements are repeated many times, then there is an optimum rhythm which, by permitting appropriate reparation, allows the maximum of effect with least expenditure of muscular power. The author considers this to be the case in almost all body movements, although experiments are not given in support of this generalisation.

The book as a whole is likely to prove of very considerable value in connection with the subject of physical degeneration, which has been for some time agitating the mind of the public. Methods of education it is now realised should, from the hygienic point of view, concern themselves with the posture of the body. In the code for 1905 issued by the Education Department stress is laid upon the importance of "the careful cultivation of a correct posture at writing and other lessons." This tardy awakening of the authorities to the importance of cultivating the bodily physique of the children who are taught in the national schools renders it probable that teachers will desire to instruct themselves in the fundamental scientific aspects of the various methods for improving the bodily structure and functions. In this respect a work such as that now under review is likely to prove of very real service; it is trustworthy, it approaches the whole question of body posture from a point of view at once scientific and utilitarian, it attacks the fundamental question (that, namely, of the effective action of the muscles), and finally, it is written in a style which makes the subject-matter intelligible without presupposing special technical knowledge on the part of the reader. The only drawback to its utility is one which is susceptible of removal by its translation into English.

F. G.

GEOMETRY OF POSITION.

On the Traversing of Geometrical Figures. By J. Cook Wilson. Pp. x+154. (Oxford: Clarendon Press, 1905.) Price 6*s.* net.

SUPPOSE that an outline figure of any kind is drawn upon a blackboard. In its construction the chalk describes a certain number of closed or open paths, a path being defined as the mark made by the chalk during the whole time of any one of its contacts with the board. But the number of paths thus actually described is not necessarily the smallest by which the figure can be produced, and it is an interesting problem to analyse a given figure into its minimum number of paths, each traversed once. As a simple example, let two oval paths be drawn intersecting in four points; the resulting figure can be traversed as one closed path. If two of the intersections are joined, the new figure can be traversed as one open path; if the remaining intersections are joined, the figure cannot be reduced to less than two paths.

The first two parts of Mr. Wilson's book deal with the problem above stated and various associated questions. The most interesting result is one of greater generality than might have been expected. Let a point in the figure be called odd or even according as an odd or even number of lines radiate from it; then a figure with $2n$ odd points can be analysed into n paths, but no fewer. (To include the case when $n=0$ a slightly modified statement is necessary, which will be found in the book.)

In part iii. the author enters upon new ground by applying the principle of duality; this is the most novel part of the book, and a few comments on it may not be superfluous. The results of the first two parts may, of course, be directly reciprocated without introducing any metrical considerations; but this is

not what Mr. Wilson does, and the consequences of his procedure are very instructive, especially from the point of view of absolute geometry. He practically confines himself to rectilineal figures, and reciprocates segments into angles, thus introducing metrical elements, and becoming necessarily faced by the complications which they involve. It is now familiar to pure mathematicians that, with an "absolute" conic to define our metrical system, there is a consistent and reciprocal definition of *angle* and *segment* (or *distance* of two points) by which each of these is the product of a constant and the logarithm of a cross-ratio. But to identify these with the expressions for angle and segment obtained by elementary methods with rectangular coordinates it is necessary to suppose the absolute conic to degenerate into one which, considered as a point-locus, is the line at infinity counted twice, and considered as an envelope is the pair of circular points at infinity. This complicated character of the absolute is at the base of all the puzzling difficulties which beset such attempts as this of Mr. Wilson's—difficulties, it is true, which he often surmounts in an ingenious manner.

For example, in the appendix he introduces a system of angular coordinates, both for lines and points, and obtains point and line equations for the ellipse. Now the unmistakable drift of his thought is that if point and line can be defined by coordinates which measure segments, then "reciprocally" line and point can be determined by coordinates which measure angles. But his angular coordinates are not really reciprocal to the segmental coordinates, as is clear from the fact that his equation of the ellipse is trigonometrical and not algebraical. It might be interesting to decide whether any simple functions of Mr. Wilson's angular coordinates are the direct reciprocals of the ordinary Cartesian segmental coordinates.

A remark should also be made on the note (pp. 120–6) on the most general form of the construction of reciprocal figures, as it may prevent possible misunderstanding. In the ordinary process of reciprocation with an auxiliary conic, F and F′ being the corresponding figures, we may say that F′ is derived from F by a process, or rule, of polarising, and that F is derived from F′ by the same rule. Mr. Wilson gives an example in which F′ is derived from F by one process, and F from F′ by another—F and F′ being reciprocal in the general sense of projective geometry. He adds that this is "wider than the usual method," which, of course, it is, if "the usual method" means employing an auxiliary conic. But the figures obtained by his method can be constructed each from the other by the general method of making four points (or lines) in F correspond at pleasure to four lines (or points) in F′, and then to every linear way of constructing F′ from F there is a dualistically corresponding way of deriving F from F′. So that it must not be supposed that Mr. Wilson has discovered any essentially new way of constructing reciprocal figures, though his remark might be misunderstood in that sense.

To return to the more popular aspect of this interesting book. The figures are, strictly, strips of black on a white ground. For the author they represent geometrical lines, and are reasoned upon as such. But the reader may give them different interpretations, and make up problems for himself accordingly. For example, let the lines in a diagram represent cuts made in a single piece of wood by a fret-saw; how many pieces are produced? What is the simplest wire model that will give a shadow like a given diagram? and so on. Stencilling, again, is full of problems analogous to those which Mr. Wilson discusses; knitting and netting give any number of examples of single-path figures. The proverb that "extremes meet" is curiously illustrated by these purely topographical questions, which suggest puzzles for children, problems for designers, and tools for logicians; while they appear with startling unexpectedness in the most abstruse mathematical theories—Abelian functions, group-theory, hydrodynamics, and electricity.

G. B. M.

ORGANIC PREPARATIONS AND THE COAL-TAR COLOUR INDUSTRY.

The Synthetic Dyestuffs and the Intermediate Products from which they are derived. By J. C. Cain and J. F. Thorpe. Pp. xiv+405. (London: Chas. Griffin and Co., Ltd., 1905.) Price 16*s*. net.

THE publication of this work is not without significance in its bearing on the oft-repeated statement that the great industry represented by the manufacture of coal-tar dyes is decaying almost to vanishing point in this country. The fact of publication presumes a demand which, in this case, must be mainly confined to those connected with, or training for, the manufacture referred to. It is unlikely that any great number of students in the colleges of this country are preparing for positions in colour works abroad, and it is therefore reasonable to assume that those concerned with the production of the book have satisfied themselves that the industry is not in such a parlous state as pessimists would have us believe. In any event, the book will powerfully influence one factor in the case—the proper instruction of students who are training for the industry.

Whether this touches the root of the matter is, however, doubtful. The gradual decline in importance of the manufacture of coal-tar products in this country has been variously ascribed to the deficient training given in the colleges, the bad patent laws, and the cost of alcohol, relatively to the conditions existing in Germany with regard to these matters. Concerning the work of the colleges, it is now generally conceded that the best of our schools of organic chemistry need fear no comparison with those abroad. The effect of our patent laws, both past and present, in handicapping the industry, has doubtless been very great; but possibly the inquiry of a Royal Commission, such as recently reported into the question of industrial alcohol, would show that, as has been conclusively proved with regard to the cost of alcohol, the effect of the patent laws on the non-

development of the English coal-tar colour industry has really been much less than has been supposed. A cause fundamental to those enumerated above, and lying at the basis of many other of our industrial lapses, may be defined as the lack of an appreciation of the importance of science on the part of the public generally. This has rendered the development of many industries quite impossible. It is reputably stated that the Badische Anilin- und Soda-Fabrik spent upwards of one million pounds sterling during a period extending over twenty years in solving the industrial problem of the synthesis of indigo. What English board of directors, even if themselves satisfied to do so, would venture to spend any such sum on apparently unproductive scientific experiments? Public opinion in this country, as reflected in the shareholders, would not allow it, any more than a six or seven years' college science course is considered a paying investment. Nor will satisfactory reform of the patent laws and the excise laws come about until the Government is made to realise, by the pressure of public opinion, that the future of the national industries largely depends upon the proper utilisation of scientific fact and method.

The work under review consists of three parts and an appendix. Part i. comprises a description of the various synthetic dyestuffs and the intermediate products from which they are derived. Part ii. gives methods for preparing typical products on a laboratory scale, but as far as practicable by works processes; and part iii. deals with the analysis and identification of dyes and with the detection of dyestuffs on the fibre. The appendix contains tables giving the specific gravities of various solutions.

The first chapter of the book gives a very short account of coal-tar and the separation and purification of benzene, naphthalene, anthracene, and phenol. A little more space might usefully have been devoted to this section.

Subsequent chapters deal with the nitration and sulphonation products of the hydrocarbons, and the production and properties of amido, hydroxyl, and carboxyl derivatives. The second section of part i. gives in seventeen chapters, occupying about one-third of the book, a systematic description of the various groups of dyes, the classification being, of course, based on the chemical constitution, and not upon the mode of application, of the dyes. The treatment of this section is excellent, the descriptions being very lucid and sufficiently exhaustive without too much detail.

Part ii., which deals with the preparation of colouring matters and intermediate products, is at once the most novel and the most useful feature of the book. It is evidently the outcome of much personal experience on the part of the authors, and the limitations of ordinary college laboratories have very sensibly been kept in view, though at the same time only such materials are employed as would be used in the technical preparation of the several products in the works.

Perhaps the least satisfactory portion of the book is the chapter dealing with the application of the colouring matters. It is very doubtful whether any useful purpose is served by such a short treatment of the science of dyeing as can be compressed into thirteen pages. Condensation to this extent inevitably results in misleading generalisation, and the authors would probably have been well advised to have referred their readers to some of the well known treatises on dyeing for this part of the subject.

The chapters on the valuation and analysis of dyes are to some extent open to the same criticism. As an example of their deficiencies, the method given for the analysis of indigo may be referred to. The method described would be entirely untrustworthy if applied to the estimation of natural indigos, and such is evidently the intention. In its main and essential sections, however, the book is a noteworthy addition to the literature of specialised organic chemistry, and both authors and publishers are to be congratulated on its production. WALTER M. GARDNER.

SCIENCE AND MYSTICISM.

Prinzipienfragen in der Naturwissenschaft. By Max Verworn. Pp. 28. (Jena: Gustav Fischer, 1905.) Price 80 pfg.

PROF. VERWORN detects mystical murmurs in the scientific camp, and is full of apprehension of coming dangers, for "mysticism is the negation of scientific thinking." Naturalists have been working out a monistic interpretation of the world, but there have been symptoms of faint-heartedness lately, especially before two questions, which the author states in the following terms:—Do vital processes depend on the same principles as the processes in inanimate nature? Are psychical processes referable to the same principles as those on which bodily processes depend? Verworn assures us that both these questions may be confidently answered in the affirmative, for the world is one, with the same principles, or rather with one principle throughout. What that "principle" is we have not been able to discover from the lecture, but we are assured that it is not a "mystical principle."

In regard to the first question, Prof. Verworn says that when we sufficiently analyse the criteria of life we find none requiring other principles than those which we require in interpreting the inorganic world. The only feature distinctive of life is the combination of potencies which are seen separately apart from life. Chemical ferments illustrate metabolism without growth; the condensations and polymerisations of chemical compounds illustrate growth without metabolism; the organism combines both. How it does so we are not told, but it is not by any peculiar vital principle. There is no need to assume a secret "organisation" transcending physical and chemical principles; there is no warrant for postulating a persistent protoplasmic architecture, either microscopic or molecular, as the physical basis of life; the form and structure of a cell is just like that of a fountain or a flame; life is a flux; "Πάντα ῥεῖ" is true throughout nature. To suppose, as Driesch, for instance, does, that an Aristotelian "entelechy" resides in

living matter and accounts for its purposive behaviour and development is to resurrect the buried concept of a *nisus formativus*. To do this is quite gratuitous, since Verworn supplies us with a guaranteed modern concept of a "self-steering" metabolism—the "self-steering" quality depending, of course, on the laws which physical chemistry has been revealing during recent years. He also assures us that there are no facts of organic being or becoming which warrant us in losing faith in the sufficiency of the monistic interpretation in terms of chemistry and physics. It is true that the illustrious physiologist has not found time in this lecture to give us any illustration of how any vital phenomenon may be formulated in terms of "the principles of the inorganic world," but he seems to have no doubt that it can be done.

As to the second question, before which so many have fallen away from monism—the question of psychical life as distinct from bodily life—Verworn finds satisfaction in boldly denying that any dualism exists. The dualistic idea was born out of ignorance fathered by desire, and it has been nurtured and refined by philosophy. The material ghost that escaped *in articulo mortis* has become a spiritual soul, but both are fallacious abstractions. It is pathetic to think of all the wrestlings with the problem of dualism since Descartes's day, for dualism is but one of man's many inventions with which he makes himself miserable. Just as the organism is a mere bundle of metabolisms, so the "ego" is but a changeful bundle of sensations, and perceptions, thoughts, and feelings derived from these—a complex the components of which are not continuously or simultaneously held in combination, though certain components, *e.g.* sensations of our body, occur so frequently and uniformly that the illusion of a persistent personality is produced. The material for the up-building of the "ego" is the external world or corporeal world—the world of sensations; the "make-up" of the "ego" is the same as the "make-up" of the world; the antithesis of soul and body is "a fossil idea." "Either everything is body in the world or everything is soul: however I like to put it, the main fact is that there is only one kind of thing." How a flux of sensations can give origin to that unified outlook and inlook which is called monism remains somewhat mysterious, but to think of any mystical principle being involved is "a negation of scientific thinking." But which is mysticism and which scientific thinking? J. A. T.

THE PLANT KINGDOM.

Das Pflanzenreich. Regni vegetabilis conspectus. Edited by Prof. A. Engler. (Leipzig: W. Engelmann; London: Williams and Norgate.)

AN account of the inception of this work was given in NATURE, October 30, 1902 (p. 657), with a list of the earliest parts. Twenty-one volumes have now been published, of which ten are devoted to monocotyledonous orders. The late Dr. K. Schumann has contributed, in addition to the Musaceæ, two memoirs on the Marantaceæ and the Zingiberaceæ respectively. In both these orders there is a large increase in numbers and a considerable amount of change as compared with the account given by Pedersen in the "Pflanzenfamilien." This is explained by the fact that an enormous number of new species have been made out of copious material received from Indo-Malaya and tropical Africa. The new species of Zingiberaceæ described for Malaya alone exceed a hundred. Dr. Schumann formulates very definite arguments in favour of the changes which he proposes in reviewing the history of the orders, and also presents a comprehensive discussion on the flower and on the relationships of the four orders which compose the series Scitamineæ.

Many of the orders are obviously too large to admit of their being treated in a single volume. The Orchidaceæ, as in the case of the "Pflanzenfamilien," have been entrusted to Prof. Pfitzer, and the first instalment contains the section Pleonandræ—formerly called Diandræ—which consists mainly of the Cypripediums as generally understood. A special feature of this volume is the list of hybrids, both natural and artificial. Similarly, the Araceæ require several parts, and Dr. Engler, who undertakes this order, begins with the tribe Pothoideæ. Dr. Engler gives a full description of the branching, and distinguishes nearly 500 species of Anthurium. A short volume includes the orders Scheuchzeriaceæ, Alismataceæ, and Butomaceæ, which are all worked out by Prof. Fr. Buchenau. Dr. W. Ruhland is responsible for the Eriocaulaceæ, and gives a detailed account of the geographical distribution, taking up the origin, evolution, and dispersal of the order. Owing to a large influx of new specimens from Brazil, the number of species of Eriocaulon now exceeds two hundred, and the genus Pæpalanthus, after being shorn of many species that form three new genera, still shows a slight increase.

The first volume dealing with a group of the gymnosperms, that on the Taxaceæ, has been written by Dr. R. Pilger. The Taxaceæ are profoundly interesting on account of the primitive forms which characterise some of the genera, but, as is usually the case with such genera, the number of species is small, and no great increase may be expected, although some new species may be looked for from the unexplored areas of China and eastern Asia.

Of dicotyledonous orders, the Tropæolaceæ, by Prof. Fr. Buchenau, appeared in 1902, and the Cistaceæ, by Dr. W. Grosser, and the Theophrastaceæ, by Prof. C. Mez, were issued in 1903. Since that time a larger volume on the Lythraceæ has been contributed by Dr. E. Koehne, who has gone very fully—in fact, more fully than seems necessary—into the varieties and forms of the more variable species. The genus Cuphea is amplified to 200 species, and the genus Rotala is extended to include some species previously assigned to Ammannia. A list of plant collectors and their contributions is added. One of the most complete and interesting memoirs is that by Prof. H. Winkler on the Betulaceæ. The general sketch contains sections on the geographical distribution and the history of the order. The fossil forms, which are numerous, are enumerated without comment, but with references,

and—a feature that one would have expected in every volume—maps are provided to indicate generic distribution.

The main purpose of the "Pflanzenreich," as contrasted with the "Pflanzenfamilien," is to provide an authentic description of species, and criticism of this work has largely to deal with considerations that are best known to the learned authors who have undertaken to write on the different orders. One of the main difficulties consists in reconciling the diverse views held by different writers who have made a special study of the same orders and groups. The discussion of certain forms under *Betula papyrifera* furnishes an instance in which Dr. Winkler holds different views from Prof. C. S. Sargent; without attempting to judge between the two opinions, it would seem that Prof. Sargent has had better opportunities of studying these forms, but it should be added that in this case the writer has fully stated both views: the ideal solution in such a case would be a collaboration of both authorities, if such a collaboration were practicable. It is from this point of view that one could have wished to see the names of other besides German botanists associated with this great undertaking; so far, Dr. Rendle, who wrote the volume on the Naiadaceæ, is the only exception. The commendable spirit of *camaraderie* which exists between botanists has been amply demonstrated in the various international meetings, of which the latest was recently held in Vienna, and it would not appear to be a matter beyond practical realisation to give a more international character to this *magnum opus*.

AN ITALIAN TEXT-BOOK OF PHYSIOLOGY.

Physiologie des Menschen. By Dr. Luigi Luciani. Ins Deutsche übertragen und bearbeitet von Dr. S. Baglioni und Dr. H. Winterstein. Dritte Lief., pp. 323+502+viii. Vierte Lief., pp. 160. (Jena: G. Fischer, 1905.)

THE general features and aims of Dr. Luciani's text-book of human physiology have already been alluded to in the review of the first two parts, and need not be recapitulated here. The first few pages of the third part complete the account of the physicochemical phenomena of respiration. The following chapter gives an excellent account of the mechanics of respiration, including the influence of the respiratory movements on arterial and venous blood pressures.

The succeeding chapter, on the nervous mechanism of respiration, is specially good, and one cannot fail to admire the mastery of the literature of the subject shown by the author, every page giving evidence of knowledge of the original sources. The subject of the localisation of the bulbar, spinal, and cerebral respiratory centres is fully dealt with, the results obtained by the earlier observers—Legallois, Flourens, Schiff and others—being well epitomised. A good *résumé* is also given of the important later results obtained by Gad and Marinescu on the localisation of the bulbar respiratory centres. Reference is also made to the interesting results yielded by Aducco's research on the action of cocaine upon the respiratory centres.

The author next gives an account of the influence upon the respiratory centres exerted by stimuli transmitted by afferent nerves. A considerable amount of space is devoted to the important work of Hering, Breuer, and others on the self-regulatory mechanism subserved by the vagi. The later experiments of Head have been omitted.

The subjects of apnœa and periodic respiration are discussed with great fulness, much of the author's own work being given.

The next chapter deals with lymph—its sources, physical, chemical, and morphological characters, its circulation, and the theories of its formation. An excellent critical account is given of the secretion theory of Heidenhain, as compared with physicochemical theories of the majority of later workers in this field. In the concluding pages of this chapter the structure and functions of the lymph glands and lymphoid organs—bone marrow, thymus, and spleen—are fully described.

The first chapter of the second volume is devoted to the subject of the internal secretions of the ductless glands. After a brief introductory account of the historical development of our knowledge of glandular secretion, the author passes to a detailed description of the structure and functions of the thyroid and parathyroids. The treatment of the physiology of the thyroid and parathyroids is so complete and full of interest that only a brief reference to the most salient points is possible. The various theories which have been held with regard to the results of removal are critically reviewed. Very full treatment is accorded to the experimental foundations for the theory of an auto-intoxication. In this connection, the results obtained by Colzi and others by means of the method of crossed transfusion are of great interest and importance. Gley's ingenious experiments on the relative toxicity of the blood serum of normal dogs as compared with that of dogs from which the thyroids had been previously removed are also fully described. An important section of this chapter is devoted to the theories of independent specific functions of the thyroid and parathyroids, and to the experimental basis on which these theories are founded.

The structure and still obscure physiology of the pituitary gland are briefly epitomised. A satisfactory account is next given of the structure and functions of the suprarenal glands, although in this case the results obtained by English workers have not been sufficiently recognised by the author.

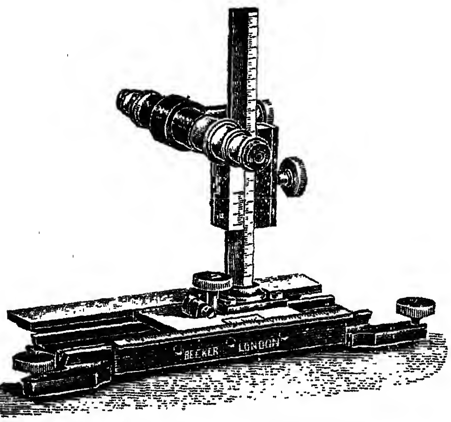
The following chapter deals with the external digestive secretions of the salivary glands, pancreas, gastric and intestinal mucosæ, and liver. The final chapter is devoted to the mechanical and chemical phenomena of buccal and gastric digestion. The account has been kept well abreast of the most recent advances, many important additions being made by the translators.

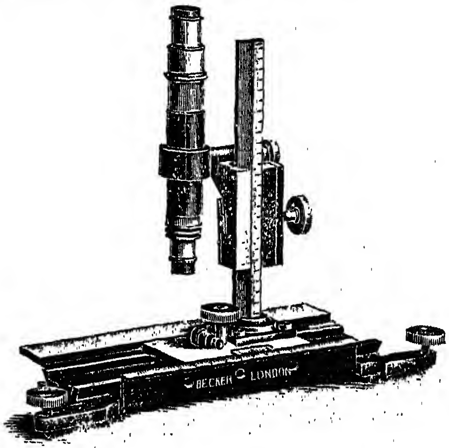
A perusal of the third and fourth parts strengthens the impression that the complete work will prove itself to be a most trustworthy and illuminative guide to modern physiology.

J. A. Milroy.

ANOTHER "NIVOC" PAGE.

(ALL PRICES ON THIS PAGE ARE STRICTLY NET.)





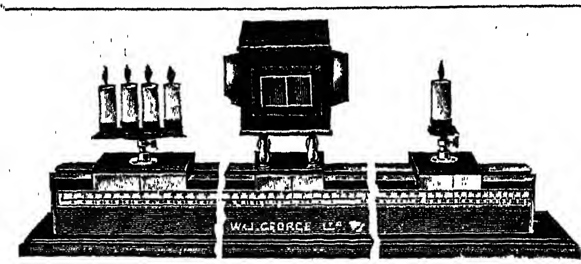
VERNIER MICROSCOPE, finest workmanship and finish and guaranteed accurate. It consists essentially of a horizontal and a vertical slide, along which the scales, 16 cm. in length, are engraved. The microscope body rotates in a vertical plane on a horizontal axis, and can be fixed in any position. The horizontal and vertical positions are marked. A glass micrometer scale giving the same reading as the verniers is placed at the common focus of the eye-piece and objective. In the instruments reading to ·02 and ·01 mm., the scales are divided on silver. A 1 in., 2 in., or 3 in. objective and one eye-piece are supplied with the instrument.

PRICES.

		£	s.	d.
A.	With scales reading to ·1 mm.	£6	15	0
B.	" " to ·05 "	7	10	0
C.	" " to ·02 "	8	0	0
D.	" " to ·01 "	8	10	0
E.	A small adjustable circular Level placed in the base of the instrument... ... ... (extra)	0	7	6
F.	A small divided Circle attached to the horizontal axis of the microscope reading to 2° ... (extra)	0	12	6

By substituting a telescope-object-glass for the microscope objective, the instrument can be used as a reading telescope, or as a small cathetometer.

		£	s.	d.
G.	Price of object-glass	£0	15	0



Bunsen's Photometer, improved pattern.

Sight box is similar to the Letheby Bunsen pattern and is fitted with a grease-spot disc (which can be removed) and plate glass reflectors. Stock pattern is supplied with candle holder as figured, but we also supply electric light holder or a gas jet burner at the same price **£2 15 0**

Improved ILLUMINATING ATTACHMENT to EYE-PIECE, for use in the adjustment of SPECTROSCOPES, SPECTROMETERS and similar instruments.

Fig. 1 shows the attachment; Fig. 2, the attachment adapted to the eye-piece.

This is a new form of apparatus for illuminating the cross wires of a telescope. It is fitted over the eye-end of the eye-piece. It has many advantages over the ordinary Gauss' eye-piece, the following among others:—

1st.—It gives a soft uniform illumination of the field.

2nd.—It can be adapted to any eye-piece.

3rd.—Each part can be easily detached to be cleaned.

4th.—Its simplicity of construction and its low price.

When ordering it is only necessary to send the eye-cap of the eye-piece; if the eye-piece is not provided with a cap, the eye-piece itself.

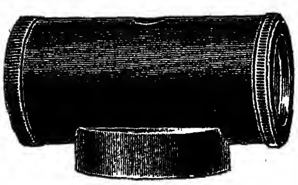


Fig. 1.

PRICE **10/6**

F. E. BECKER & CO. (W. & J. GEORGE LTD. SUCCESSORS), **33-37, HATTON WALL, LONDON.**

RICHARD CLAY AND SONS, LTD., BREAD ST. HILL, E.C., AND BUNGAY, SUFFOLK.

in working, this high pressure must be transformed down into a low one at the distant end of the transmission system.

But what did high pressure—produced with a dynamo—mean twenty-six years ago? Why, three or four hundred volts—what, in fact, is called low pressure to-day—a pressure less than is now often used for lifts in buildings, pumps in mines, and tramcars in streets. And how was it proposed to transform this so-called high pressure into a low one? Why, I suggested mechanically coupling a 400-volt direct-current motor to a 50-volt direct-current dynamo—the device that has since been called a "motor generator"—and such a combination was shown in operation at that lecture.

But it was in Paris, at the Palais de l'Industrie, the home of that electrical exhibition of 1881 which has now become classical, that modern electrical engineering was born, and shortly afterwards *Punch* exhibited the young infant thriving, and imbibing liquid nourishment from a storage cell.

"What *will* he grow to?" says the picture. What *has* he grown to? Aladdin's ring, Aladdin's lamp—whose slaves brought a fortune to him, and a fainting fit to his mother—were but poor magic makers compared with the ring evolved by Gramme and that boy, Paccinotti—compared with the lamp constructed by those veterans Edison and Swan.

In the "Arabian Nights" it is stated that Aladdin's would-be uncle, the noted and learned African magician, knew that the wonderful lamp was not fed with oil, and he anticipated by many centuries the plan for reconciling the inhabitants of Johannesburg to having the electric pressure in their houses raised from 110 to 230 volts—for did not he, like the municipal African magician, offer "new lamps for old?"

It is also described how the lamp enabled Aladdin to carry off the Princess Badroulboudour, and the wicked uncle to transport the palace. But electric traction has carried off whole neighbourhoods out of cities into suburbs, and, by transporting hundreds of thousands daily, has helped to solve the problem of housing the working class; while electric distribution of power has discovered, not caves of buried jewels, but waterfalls of ever-flowing wealth.

At the mines near Silver City, Idaho, for example, coal had reached seventy shillings a ton, wood thirty-six shillings a cord. For years the distribution of power was by donkeys, or by long teams of horses slowly hauling heavy loads of wood up the mountain road; and then the magician of this, the electric age, came to Idaho, and what those mines need—power, clean, dustless, weightless power, now courses up the mountain side from Swan Falls on Snake River in the valley below. What fairy of old, who could change dead leaves into jewels, ever worked such beneficent wonder? See how proudly those posts look down upon their conquest of the past. For have they not brought an end, not merely to wasteful extravagance in lifting fuel up to those mines, but also to needless toil for tired cattle?

In 1886, when the boy Electricity was five, the babe Johannesburg was born, and the two youngsters have raced along neck and neck. To-night I will tell you something of their lives.

Nine years after that first lecture, the British Association honoured me by asking for another. In 1888, however, it was beginning to be realised that a pressure of 2000 volts between electric mains might not make too great a call on the funds of life insurance companies. Alternate current transformers had come into use; Ferranti was employing them practically, for distributing electric current from the Grosvenor Gallery, Bond Street. A "transformation scene" Lord Kelvin called the apparatus at that lecture. The male white population of Johannesburg was now—2000.

But, although current, at 100 volts pressure, was beginning to be distributed for electric lighting, the distribution of power for working electro-motors was still but a dream of the future.

In exactly a decade after the Paris Electrical Exhibition of 1881 came the Frankfort Exhibition of 1891. More than ten times 2000 volts was there used to transmit more than 100 horse-power, more than 100 miles, with more than 75 per cent. efficiency.

A death's-head and cross-bones were painted on every post along that 100 miles of railway line, Lauffen to Frankfort, for he who should touch those bare wires, with a pressure of 25,000 volts between them, secured electrocution; and a similar suggestion of mortality greets the wayfarer—in his own language, be he English or Dutch—on the posts of the Rand Central Electric Works.

	1882 Hirschau to Munich	1883 Vizille to Grenoble	1886 Creil to Paris	1891 Lauffen to Frankfort
Pressure at transmitting end in volts	700	3000	6000	25,000
Horse-power delivered by electro-motor ...	5·8	7	52	114·2 to lamps
Distance in miles ...	3·5	8·75	35	108·7
Percentage commercial efficiency of transmission	36	62	45	75·3
Diameter of line wire in inches	0·18	0·079	0·2	3 wires each of 0·158
Material of wire... ...	—	Silicium bronze	Copper	Copper

The table shows that the use of higher and higher pressures has enabled larger and larger amounts of power to be transmitted longer and longer distances, with greater and greater efficiency, that is, with less and less waste. Now, why is this?

The electric current, as you know, is used for lighting buildings, driving machinery, propelling cars and trains. But throw away the notion, if any of you still have it, that electricity is a kind of gas, or oil, or fuel that is used up in these operations. The common expressions, buying electricity, consuming electric current, are most misleading, for just as much electricity flows away per minute—through the return conductor—from your electrically lighted house as flows to it through the coming conductor. If, therefore, it were electricity that you had undertaken to pay for, you must have made a very bad bargain, because you do not retain the smallest portion of what you would have agreed to purchase.

The electric current is like a butcher's cart carrying round meat—you no more consume current than you consume cart. It is not the vehicle, but what it leaves behind that the consumers buy—meat in the case of the butcher's cart, and energy in the case of the electric current.

Exactly the same considerations apply to the distribution of power, with air at 70 lb. pressure per square inch, to the thousands of rock drills on the Rand, to the distribution of power with water at 425 lb. pressure per square inch down the shaft of the Rietfontein Mine, and at 750 lb. pressure in the workshops of the Central South African Railways at Pretoria.

The energy conveyed with air, with electricity, or with water is made up of three factors—(1) the current, (2) the time during which it flows, and (3) the pressure under which it flows; while power depends on the current and the pressure only.

Few words are used more vaguely than this one "power." Before starting for South Africa some of us gave someone a power of attorney; we came on a ship of 12,000 horse-power; the voyage did us a power of good; at the concert on board we sang of the power of love.

In engineering, however, power has one very definite meaning—the rate of doing work—and a stream of air, of electricity, or of water exerts much power, that is, works rapidly, when it quickly loses pressure, or head. Quickly losing one's head, however, is not characteristic of large brain-power, and the power exercised by those who sit in high places is often much in excess of their rate of doing any kind of work.

When water has but a few feet of head, the quantity flowing over a water-wheel must be large if much work has to be done. But since the water usually comes to a

low pressure wheel along an open stream, and flows away again also along an open stream, no expense has to be incurred in laying down large pipes. If, however, it were necessary to distribute much power over considerable distances through a pipe conveying such low-pressure water, the pipe would not only have to be long, but of large cross-section, and, therefore, very bulky and costly. For example, this model is a full-size representation of the transmission of only one horse-power with low pressure.

On the other hand, if the water possesses considerable head, the transmission pipe may be of small diameter. In this second model the three-cylinder pump produces a pressure of 425 lb. per square inch, exactly the pressure used in the hydraulic transmission of power down the shaft of the Rietfontein Mine, and with that pressure less than four gallons of water flowing per minute through this three-quarter inch pipe gives as much power to this turbine as would be delivered by 825 gallons pouring per minute over this water-wheel four feet in diameter.

The water pressures in these two illustrations bear about the same proportion to one another as the electric pressure in the Lauffen-to-Frankfort transmission bears to the electric pressure usually maintained between the terminals of a lamp in Johannesburg.

The value of using pressure water is grasped when you realise that at the Rietfontein Mine, by circulating about 85 gallons of water per minute, at 425 lb. pressure per square inch, through a pipe 16 square inches in cross-section, not only is the circulating water all returned to the top of the mine, but in addition 144 gallons are pumped up per minute from a depth of 546 feet through a pipe $38\frac{1}{2}$ square inches in cross-section.

The water supplied by the London Hydraulic Power Company at 1700 feet head, although not filtered, costs nearly four times as much per gallon as the filtered water furnished by the Metropolitan Water Board. In England dirty pressure water is a relatively costly commodity, sparkling drinking water a relatively cheap liquid. In Johannesburg, on the other hand, until quite recently, the charge for drinking water was ten shillings a thousand gallons, plus two-and-six a month for meter rent, or about twenty times the London rate—the temptation to drink other things in Johannesburg must have been very great. Now, since the establishment of the Rand Water Board, it is six shillings a thousand gallons, which, without meter rent, is still ten times the London price, so that liquid with a head in London is still cheaper than plain drinking water here.

In the distribution of power, current and pressure are equally important. It is not merely because, even this month, August, after a phenomenally dry season, about 5,000,000 gallons of water are rushing per minute over the Victoria Falls, but it is because this water also thunders down about 380 feet that these falls are a potential source of power.

The Howick Falls, near Pietermaritzburg, have nearly as much head as the Victoria Falls, and twice as much as Niagara, while a syphon of soda water, when the gas is first pumped in, holds its head higher than any of the three. But, although in Johannesburg you probably pay a shilling for a syphon of soda water as an energy-producer in man, it is not worth 1/10,000th part of a penny as an energy-producer in a turbine, there is so little of it—only a pint and a half.

Probably, like myself, you have heard vague comparisons made between the power of the Victoria and the Niagara Falls. Now, what is the true comparison?

The flow at Niagara varies at different times of the year from about 62 to 104 million gallons per minute. At the Victoria Falls the flow can be as little as one-twelfth of the smaller number—for it is so now; and some authorities, well acquainted with the spot, say that at the end of another three months the flow will only be half of even that. The mean available drop at Niagara is about 160 feet; at the Victoria Falls about 380 feet. Hence, while the *minimum* Niagara flow represents about 3 million horse-power, the *present* Victoria flow represents about 580,000 horse-power, or only about one-fifth of the Niagara flow. Further, if those who predict the flow of the Zambesi sinking to something like $2\frac{1}{2}$ million gallons per minute in November are true prophets, the Victoria Falls will then only give out about 300,000 horse-power, or, say, one-tenth of the *minimum* that Niagara produces.

In all that precedes, I have taken the full power of the direct drop in each case; that is, I have assumed in each case the intake to be close to the main drop, and I have deducted nothing for inefficiency of machinery.

Now, how exactly does the efficiency in the electric transmission of power depend on (1) the pressure, (2) the power transmitted, (3) the length of the transmission line, and (4) the resistance of the conductors composing it?

The very simple approximate formula connects these quantities:—

$$\left.\begin{array}{c}\text{Percentage}\\ \text{loss of}\\ \text{power on}\\ \text{the road.}\end{array}\right\} = \frac{\text{Horse-power transmitted}}{3\ (\text{thousands of volts})^2} \times \text{miles} \times \left\{\begin{array}{c}\text{Resistance}\\ \text{per mile of all}\\ \text{the conductors}\\ \text{in parallel.}\end{array}\right.$$

This formula tells us that as long as the electric pressure is limited to some 10,000 or 11,000 volts—a pressure boldly used as early as 1897 by the Rand Central Electric Works, and at the Moodie Mines, near Barberton, but the one that is still the maximum sanctioned in Great Britain—it will not be possible, even with a pair of conductors of good copper, each as thick as the one I hold in my hand, viz. three-quarters of an inch in diameter, to transmit more than about 6000 horse-power, or to transmit that power more than about 10 miles, without the loss on the road exceeding 10 per cent.

The actual efficiency will, of course, be less than 90 per cent., since there will be losses also in the machinery at each end of the transmission system.

If, however, the electric pressure be doubled, that is, raised to 20,000 volts, then through this pair of conductors (kindly put up by the Transvaal Technical Institute, to bring power from their dynamo room to this hall), which are not much more than one-fifth of the cross-section of the former, and therefore not much more than one-fifth of the cost, as regards copper, we can transmit 2700 horse-power 23 miles, and still only lose 10 per cent. on the road.

Now Brakpan, where is the generating station of the Rand Central Electric Works, is almost exactly 23 miles from Johannesburg. Six wires come thence to Johannesburg, three of which may be likened to the going conductor, and three to the return in a two-wire system like this, also any three of those wires have a joint cross-section rather larger than three times the cross-section of this. Hence, with 20,000 volts, about 8000 horse-power could be sent to Johannesburg from Brakpan through the existing wires with only 10 per cent. loss on the road, or about 3400 horse-power (which is rather more than the entire maximum output of that generating station on any occasion last year) could be sent with only 4 per cent. loss.

I should have liked to show you this experimentally, but Mr. Reunert, Principal Hele Shaw, and Prof. Dobson, who, since my arrival, have so kindly put themselves to so much trouble to give expression to my wishes, might have thought me a little exacting had I asked for a lecture hall big enough to include a transmission line from Brakpan; and so, instead of this pair of conductors connecting two places 23 miles apart, I am going to employ a pair of extremely fine wires, each less than 1/100th of the diameter, that is, less than 1/10,000th of the cross-section—so fine, in fact, that you cannot see them.

Switch on the current, more than 100 lamps glow. Now think of a wall of lamps ten times as high, then ten times as wide, and then six times as big as all that, and you will have 2700 horse-power; and that is the power which, put into this pair of wires 23 miles away, say at Brakpan, with this pressure of 20,000 volts, will cause about 2400 horse-power to come out at Johannesburg.

This experiment of transmitting *five* horse-power across the hall is the nearest approach to wireless transmission of power that I have ever seen. But there are wires, although invisible, for if I make them touch at one point with this long stick a flash occurs above your heads, and the glow lamps on the platform go out.

I directed your attention to the fact that in 1888 the male population of Johannesburg was 2000. By 1896, according to the census taken that year, it had grown to 32,387. Now, curiously enough, in 1897 two transmissions

were arranged for at 33,000 volts—the one at Crofton, California, and the other at Redlands, California; and no pressure higher than that used on the Lauffen-Frankfort transmission seems to have preceded this 33,000 volts anywhere in the world. Indeed, it would almost appear as if electrical engineers were waiting to use a higher pressure than 25,000 volts until the publication of the census of Johannesburg.

In 1898 the highest working pressure in the world was 40,000 volts for a 34-mile transmission at Provo, in Utah, and the male white population in Johannesburg was also about 40,000. Then came the war, and volts beat white man, for, according to the census of last year, while the white male population was 52,106, there were several examples of transmissions at 60,000 volts, as seen from the following table.

Year	From	To	Country	Transmission distance in miles	Horse-power transmitted	Pressure at transmission end in volts
1897	Crofton	—	California	—	—	33,000
,,	Redlands	—	,,	—	—	,,
	—	Bangalore	India	92	4,300	35,000
1898	Provo	—	Utah	32	—	40,000
—	Gromo	Nembro	Lombardy	22	3,300	,,
—	Logan	SaltLakeCity	Utah	150	2,600	,,
—	Canyon Ferry	Butte	Missouri	70	5,700	50,000
—	Shawingan	Montreal	Canada	90	15,000	,,
—	Moutiers	Lyons	France	112	—	57,600
—	Spokane	Washington	—	100	3,000	60,000
—	—	Guanaguato	Mexico	104	4,000	,,
—	Electra	San Francisco	California	147	10,000	,,
—	Colegate	Stockton	,,	218	5,000	,,

But with the influx of the white members of the British Association doubtless the tide will turn, white man will make a spurt and catch up electric pressure, and in this respect, at any rate, the Witwatersrand will become a white man's country.

Indeed, not only have various successful 60,000-volt transmission schemes been carried out, but the Kern River Power Company in California is constructing one for transmitting 4020 horse-power over 110 miles at 67,500 volts.

Transmission at 67,500 volts over 110 miles. Why, when the new railway—Brakpan to Witbank—is completed, 110 miles will be 20 more than will separate the Rand from the coalfields at Witbank—fields that produce such good coal that the Central South African Railways have contracted to purchase 84,000 tons during this year, at six shillings per ton at the pit's mouth. Now, at a pressure of 67,500 volts, these two small wires could, without becoming too warm, bring about 9000 horse-power from Witbank and deliver 7600 of it to the Rand.

Or if six wires were used like those now employed by the Rand Central Electric Works, then, at 67,500 volts, 9000 horse-power might be put in at Witbank and only 5 per cent. lost on the road, that is, about 8550 horse-power delivered on the Rand.

But the insulators would have to be placed much farther apart than on the existing Rand posts to prevent the starting of a brush discharge between the wires—a subject to which I will return.

You will now grasp why in 1895, ten years ago, it was a bold and pioneering policy to equip the Rand Central Works for 10,000 volts, and to use 13,000 volts during times of full load, and why in 1905 the recommendation of some advisers to distribute power at only 10,000 volts to the proposed substations of the contemplated 57 miles of electrified railways—Springs to Randfontein—is most retrograde of those advisers to the railway.

In 1879, a firm of electrical contractors, well known then, and equally well known now, told me that they had been asked to tender for the construction of an electric transmission system to convey a comparatively small amount of power 10 miles. But since they considered that they could not possibly hope to deliver more than half, while, in practice, they feared that they would only succeed in delivering much less, the proposal had to be ranked with the exploits of Gulliver and Baron Munchausen, and so even that firm declined to tender. To-day, twenty-six years later, electric power is, from an engineering and from a business point of view, being successfully transmitted 232 miles—nearly as far as some of you took fifteen hours the night before last in being transmitted from Ladysmith.

Now, how are these electric pressures of 10, 20, 30, 40, 50, 60,000 volts produced? Why, by means of the alternate current transformer, which does for electric power exactly what the lever does for mechanical power. Exert a small force through a long distance at the long end of this lever, and you have a large force exerted through a short distance at the short end. Apply a small electric pressure with a large current at one side of this transformer, and you have a large pressure with a small current at the other. But there are no moving parts, therefore the arrangement is called a "static transformer." It requires no adjustment from day to day, therefore it may be kept entirely immersed in oil to improve its insulation.

Such statical transformers I used to step up the pressure from 100 to 20,000 volts at the transmitting end, and to step down the pressure from 20,000 to 100 volts at the lamp end in the last experiment. Everything looked quite harmless until I intentionally brought the transmission wires into contact. So does the transformer, immersed in a huge cylinder of oil, now projected on the screen, although it regularly produces 60,000 volts, and can supply 1100 horse-power at that pressure. So does this water-cooled transformer (the interior of which is seen in an X-ray picture to the right, and the exterior to the left), although it can supply 2000 kilowatts, that is, 2700 horse-power. Its size can be realised by comparing it with the tiny transformer by its side—the size of the one which I have on this table.

60,000 volts, well, what of it? some of you may say. It cannot start a discharge between even sharp needle points separated by a greater distance than about six inches, and some of you have produced such a spark with an electrical machine—I am producing such a one now.

But each time that a spark passes between the terminals of the electrical machine the pressure is relieved, so no arc is maintained. Bring the terminals of that transformer within six inches of one another, however, and a roaring arc of 2700 horse-power will be kept up, dealing destruction around.

Let me show you a spark started with a 70,000-volt transformer when supplied with only one horse-power. What a banging is produced. Now picture to yourselves what would be the result if the power were not of one, but of 2700 horses, such as that transformer can furnish.

The photographs show the sort of discharge that may occur over the surface of an insulator 1 foot high—such as is used on a high voltage transmission line—when the testing voltage is 80,000 in this case and 105,000 in that, and when there is plenty of power to maintain the arc. It is veritable lightning, not a mere flash, but a continued flame; and the sort of insulator that is used in practice for a 70,000-volt transmission is realised by looking at the specimens, which are only intended for 10,000 volts.

There is nothing new in high voltage by itself—it existed in the period of the frictional electrical machine more than 100 years ago, but it was associated with only a very small current; next, dating from the development of the dynamo, came the low voltage large current period; and now we have entered on a third era, the high pressure moderate current period, that is, the period of high pressure combined with horse-power.

Next I come to a very important question, and one that merits far more consideration than it has yet received. There are two kinds of electric current—direct current and alternating current. Direct current is like a continuously flowing stream of water, such as, for example, the one that flowed through this pipe and drove this turbine. Alternating current, on the contrary, is like this band, which, although swinging backwards and forwards, also turns a wheel in one direction at the other end. Now, which kind of electric current should be used for the dis-

tribution of power over *long distances*? Practically, every electrical engineer will at once reply, alternating, of course. Well, I am going to preach heresy. I say direct current!

The alternating current has undoubtedly the great advantage that a motor can be constructed with no rubbing electric contacts, every wire may be permanently soldered in position, a condition of considerable importance in dusty places like mines. Here is such a motor—the first polyphase motor ever sent from America to Europe, the first ever seen in Great Britain, constructed seventeen years ago by Tesla with his own hands, when he was too poor to employ a workman.

Another advantage possessed by an alternating current is that an alternating current dynamo can be constructed to produce a large horse-power at a high voltage, and further, as we have already seen, this alternating voltage can be transformed into a still higher one without the use of moving machinery.

This is one of the five largest dynamos in the world. Its size you can better estimate by looking at the ring standing on end, now projected to the left. The latter is the stationary portion of a 5000 horse-power horizontal shaft dynamo, while the photograph to the right is that of a vertical shaft machine of double that power, viz. a dynamo that can develop 10,000 horse-power at a pressure of 11,000 volts. Fifteen years ago, Ferranti—the Brunel of electricity—spent a mint of money constructing some of the parts of a 10,000 horse-power, 10,000 volt alternator, which were, however, never put together. This dynamo projected on the screen stands complete, with its four sisters, in the Canadian Niagara Power House, and the tests already made show that its efficiency reaches the extremely high value of 98·2 per cent., that is, 1·8 per cent. of the power developed is sufficient to cover all losses. Ferranti's dream is more than realised, and the old story is repeated. We break up the pioneer leviathan, the *Great Eastern* steamship, as a great unwieldy giant very weak in its knees, a little later we build the *Baltic*, a third as large again, and with twice the engine power.

Without any transformation at all, these dynamos will economically drive machines some miles away, and, with the pressure transformed up from 11,000 to 60,000 volts, power will be distributed in Toronto, 85 miles away from the falls.

Contrasted with this, no single large *direct* current machine has ever been constructed to generate more than about 3500 volts, and no means is known for efficiently converting a direct current voltage into a higher, or a lower one, without the use of moving machinery.

So far, then, my case seems weak! The advantages of using great electric pressures we have seen. Are there any disadvantages? This is a disadvantage, the risk of piercing the insulation! See how thick the insulating material has to be on cables, how far apart the conductors have to be placed, even when the cable is intended for only 10,000 volts. But does this consideration supply any argument for or against the use of one kind of current rather than the other? Small current and high pressure must be used for the economical transmission of power over long distances, whether the current be alternating or direct, I agree; but, ladies and gentlemen of the jury, I submit that, while from the point of view of economic transmission, 60,000 volts alternating means exactly the same as 60,000 volts direct, from the point of breakdown of the insulation, 60,000 volts alternating is as bad as 85,000 volts direct, indeed may be worse than 100,000 volts direct. For an alternating current consists of waves like the waves of the sea. In a storm, the waves may be running mountains high, and yet the average depth of the sea remains the same as in a calm. But what does it benefit the poor passengers, when tossed helplessly backwards and forwards in their berths, and feebly calling "steward," to be assured that, although the waves be peaked, and the maximum elevation large, the square root of the mean square of the amplitude of oscillation is quite consistent with perfect internal tranquility? And so feels the poor insulating material—the mean electric pressure may not be very large, and yet the crests of the waves may be so high, and the troughs so low, that its strength cannot stand the electric tossing.

Each of those waves of electric pressure on the diagram gives the same reading on a voltmeter, but the peaked one has far more destructive action than the flat topped one.

But there are other disadvantages in the use of alternating current. This coil of wire represents one of the conductors which, when unwound, might join two places, the one where incandescent lamps (for example) have to be made to glow, and the other where is the water-power which drives the dynamo that generates the current. If a *direct* pressure of 100 volts be applied at one end of the system, the lamps at the other end glow brightly, as you see, whereas if now I apply an *alternating* pressure, although of exactly the same value, the lamps are quite dull.

The explanation of this striking difference is that in such a case only a fraction of the *alternating* pressure is used in making the lamps glow, the remainder being employed in maintaining a rapidly reversing magnetic field.

This magnetic effect—this self-inductive effect as it is called—is small if the going and return conductors be straight, short, and near together. But if the distance over which the power is to be transmitted be long, the wires obviously cannot be short, and if to obtain economy high electric pressure be used, the wires cannot be put very near together, since that would lead to a brush discharge through the air from one conductor to the other, producing leakage.

Indeed, the minimum distance that must separate the conductors has to be increased very rapidly with the pressure unless their diameter is greatly increased at the same time. The table gives this minimum distance for conductors 1/10th, 2/10ths, and 4/10ths of an inch diameter respectively, and it will be seen that increasing the thickness of the wire greatly diminishes this minimum. For instance, at 80,000 volts, doubling the thickness of the wire from 1/5th to 2/5ths of an inch diminishes the minimum distance from 6½ feet to 13½ inches.

JOHANNESBURG.

Elevation, 5689 feet, January, 1905. Barometer, 24·3 inches. Temperature, 91°·5 F.

Minimum distance that must separate two parallel wires to prevent the starting of a Brush Discharge.

Root mean square electric pressure in volts between wires	Diameter of wires in inches		
	1/10	2/10	4/10
40,000	8·8 in.	—	—
50,000	32·2 in.	—	—
60,000	9·9 ft.	14·7 in.	—
70.000	35·7 ft.	33·8 in.	—
80,000	—	6·5 ft.	13·6 in.
90,000	—	—	23 in.
100,000	—	—	38 in.

It must, of course, be remembered that these are minimum distances, and that the distances apart at which the wires have actually to be fixed in practice are much greater.

But that is not the whole indictment against the use of alternating current for *long distance* transmission. Leakage from wire to wire can be rendered small, but still, if the current be alternating, it always flows along the wires, even if all the apparatus at the distant end be entirely disconnected from them. Let me show you this.

I apply a direct pressure of 100 volts, and no current enters the transmission line, for it is well insulated along its length and at its ends. I apply instead an alternating pressure of the same value, without making any other change, and you observe a very perceptible current. The very first thing that struck Ferranti when he commenced transmitting power with alternating current at 10,000 volts pressure, from Deptford to London, was that the current flowing into the system at Deptford was as large during the daytime, when practically no lamps were turned on in London, as during the evening, when many were glow-

ing. Again, in the case of the 150 miles transmission, at 50,000 volts, by the Bay Counties Power Company, in California, it was found that to charge even the aërial lines as a condenser required 40 amperes, so that the current flowing into the system remained practically unchanged when the useful load was decreased from several thousand horse-power down to nought.

Now this is the very opposite of the effect we previously noticed, for in that case it was the alternating pressure that left the lamps dull by failing to send enough current into the transmission system. Surely, then, the one effect is a correction of the other. That is so, and I will give you a practical illustration.

I have here two transmission lines, the one with its going and return conductors placed far apart so as to exaggerate the first effect, the other with its going and return conductors near together to exaggerate the second effect; indeed, as I am employing for this experiment only a pressure of 100 volts, there is no risk of brush discharge, and so I have put the wires extremely near together on the second transmission line. The alternating current produced by the dynamo divides itself between the two transmission lines, and the two branch currents are about equal.

But, as you may see by means of the oscillograph—an instrument developed in my laboratories by Mr. Duddell, one of my students, for giving us a picture of the current and pressure waves in each of the two circuits—there is a great difference between the waves in the two circuits. In the transmission line with the wires far apart, the reversals of the alternating current occur after the reversals of applied pressure, the crests of the current wave lag behind the crests of the pressure wave, whereas in the case of the transmission line, with the wires very near together, the exact opposite occurs, viz. the crests of the current wave are in advance of the crests of the pressure wave.

Now, in the circuit coming from the dynamo, both current waves exist together, and as the crests of the one wave coexist with the troughs of the other there is interference, and the result is practically no current at all. So here we have the rather surprising result of practically no current in a main circuit, and yet a considerable current in each of the branch circuits into which the main circuit divides.

This may perhaps be regarded as a beneficial result, and should be added to the score of alternating current. But just as a very small alternating current in the main circuit can be split up into two large currents in the branch circuits, a small alternating pressure can be split up into two large alternating pressures, and in that case the result must be scored against the use of alternating current.

In this experiment I use also two circuits, one with the conductors very far apart, and the other with them very near together; but instead of employing these circuits as two *branch* transmission lines I put them end on, so that they constitute *successive* portions of the same transmission line. An alternating pressure of only 100 volts is provided by the dynamo and applied to the whole arrangement, and yet you observe that, between the going and return conductors in that part of the circuit in which they are far apart, as well as in that part in which they are near together, a pressure exists of 2400 volts, which is twenty-four times as great as the entire pressure supplied by the dynamo to the mains.

This result with alternating electric pressures is not unlike that obtained with mechanical forces when a small force is resolved into two very large ones, with each of which it makes nearly a right angle.

Much damage has been done to electric cables, used for the distribution of power, by these unexpected high pressures produced by resonance in alternate current circuits. A cable may have been tested at twice or thrice the working pressure and passed as satisfactory. But if there is a liability of a pressure being applied, which, as you see, may in somewhat extreme cases be twenty or thirty times the working pressure, what avails it that there is a factor of safety of 2 or 3?—disaster must follow.

Now with direct current for long distance transmission there is no question about the electric pressure at the top and bottom of a wave being much greater than the mean pressure, no question about self-induction reducing the current—no objection, therefore, to putting the conductors as far apart as the risk of brush discharge may necessitate—no question about capacity current, no resonance troubles, &c.

I wonder whether any of you are thinking—Well, perhaps there may be something in this heresy after all. No? Oh! then you are thinking, if the arguments were sound, the direct current system would have been already employed for long distance transmission. Well, but it has! Power up to 3000 horse has been transmitted with direct current, at 14,000 volts, from Combe Garot to Le Locle and La Chaud de Fonds, round a circuit 32 miles long; 4600 horse-power has been transmitted with direct current, at 23,000 volts, 35 miles from St. Maurice to Lausanne; and a transmission system for 6000 horse-power, at 60,000 volts, over 114 miles from Moutiers to Lyons, is in course of construction.

Another advantage that is possessed by all these examples of direct current transmission carried out by M. Thury is that it is the current that is kept constant and the electric pressure that is automatically raised when the demand for power is increased, whereas with the ordinary alternate current system it is the pressure at the lamp end that they aim at keeping constant, and the current that varies automatically with the demand for power

Now it is far more easy to maintain the constancy of the current flowing round a long circuit than to prevent the bobbing up and down of the electric pressure at the distant end of a long transmission line, and that irritating dancing of the lights, with which Johannesburg is so familiar, would be particularly difficult to avoid if the transmission line were long and the electric pressures at its two ends differed by some thousands of volts.

Constant current has also its well known disadvantages, but these would not come into play if the constant current were not taken into houses, mines, &c., but used to drive motor generators in substations, the dynamo portion of the motor generator being of any type desired.

The pioneering development that American boldness, enterprise, initiative, and originality have brought about in the electric distribution of power, combined with the extraordinary commercial success that it has won on both sides of the Atlantic, have made people ask, "Is such an industrial revolution in store for South Africa?"

At first sight one is inclined to answer "No!" This country is dotted with coalfields—coalfields blacken the map, and the produce of some of them is reported to be nearly equal to the best Welsh coal in quality. A humorous English paper said that I was going to give this lecture standing on a coal waggon to indicate how superior, as a carrier of energy, was a coal cart to a current.

When, on the one hand, one hears that good coal is brought from Witbank and delivered to the mines on the Rand at 13*s.* a ton, and that even this price will be lowered on the completion of the new railway from Witbank to Brakpan, one feels that long distance electric distribution has not much chance—indeed, a proposal to burn slack coal at Vereeniging, only 33 miles from Johannesburg, and electrically distribute the power on the Rand, fell through.

On the other hand, when one finds that at the Wankei coalfields themselves large coal costs 15*s.* a ton *at the pit's mouth*, and that Salisbury pays 36*s.* 5*d.*, Umtali 43*s.* 6*d.*, and Kimberley 67*s.* per ton, one feels that electric distribution in this country possesses possibilities.

South Wales has many coal mines—cheap slack coal lies heaped at the pit's mouth. Let me put this question to you: "If an electric supply distributing company were to start in South Wales to obtain their electric energy, *not* from waterfalls, mark you, but from coal brought to their generating stations from coal mines, would you anticipate, I ask, that such a company would obtain customers for their electric energy at coal mines themselves?" "No, emphatically no," you would reply, for that would be taking coals to Newcastle with a vengeance. Yet, what does that map tell us? Why that, within four years since that South Wales company was merely applying to Parliament for an Act to enable them to establish a distribution of power system, fourteen of the largest colliery

companies and thirty of the mines are taking power at about one halfpenny a horse for an hour, the demand three months ago having reached 13,000 horse-power, and rapidly increasing.

That the North-Eastern Railway, and such a large number of manufactories along the Tyne, should, as seen from that other diagram, take power from the Tyneside Electric Power Supply Company—which also has been but four years in existence—was perhaps to be expected, but that coal mines should obtain power by the burning of the product of distant collieries resembles at first sight the method of earning a living attributed to a certain village, viz. by taking in one another's washing.

But this result is but an example of the subdivision of labour. At a coal mine getting coal, and at a gold mine getting gold, is the business, and at both, especially in the early days of sinking the mine, it should pay better to buy electric energy from an outside source than to generate the current on the spot.

Niagara sends 24,000 horse-power to Buffalo, 30 miles away, and sells it at 0.7*d.* per horse-power hour to an eight-hour user there—a price which is *not* cheaper than the total cost of generating a horse-power hour at Buffalo with a *large* steam engine. But tapping electric wires to obtain any amount of power that may be needed, and just at the time that it is required, is far more convenient than erecting steam engines and getting up steam, and certainly cheaper in the early days of sinking a mine.

It has been objected that the total steam-power curves of all the gold mines on the Rand show the same sort of falling-off during the hours 4 to 7 a.m. and 5 to 8 p.m., and, therefore, that, apart from using larger and more economical engines, and from diminishing the cost of superintendence for the energy sent out, there would be no saving by supplying many mines with electric power from a common generating station. But if there be a railway in the neighbourhood, largely used by workmen, the slack hours on the mines will be the busy hours on the railway. Hence, if that railway be run electrically from the same generating station, the load curve will be flattened and much improved.

On the Rand, however, there is an indisposition, apparently, to utilise distribution of power on a large scale. The labour conditions in this country are certainly peculiar. My friend Mr. Denny, in his book on "Deep Level Mines of the Rand and their Future Development," expresses this opinion—and there is no man whose opinions on such matters I value more highly:—"It has, however, been fairly conclusively proved that in average conditions hand labour is both speedier and cheaper than machine drilling."

But when one watches this hand labour one thinks of this picture rather than that. Contrary to American and Australian experience, it may be true that in this country white men and machinery may be dearer and slower than black machinery and man rolled into one. But it makes one uncomfortable, even unhappy, to think it possible, for it means that the muscular machine is more valuable than the inventor's brain.

Another objection felt by mine owners here to investing much capital in machinery is the somewhat uncertain character of their business, and a third against a mine depending for a supply of power on an electric current coming from a distance is the climatic conditions.

South Africa has various unique big things, but it has not a monopoly of big atmospheric disturbances, and these disturbances do not prevent electrical distribution of power schemes being pushed forward by leaps and bounds in the other three quarters of the world—the list given on p. 615 is merely a selection from some of those using the highest working voltages. During my short stay in this country I have been giving this matter much consideration. Without stopping this evening to discuss the subject in detail, I may mention that, after the admirable work of Mr. Wilms, Mr. Spengel, Mr. Heather, and others here on the improvement of lightning arrestors for electric transmission lines, I think I also see my way to putting a nail into the coffin of these bugbear lightning troubles.

But while advocating electric transmission of power I should not start by constructing a transmission line from the Victoria Falls to Johannesburg; and I say that, not because I am of opinion that it could not be made to work, nor that, if direct current were used, it could not be relied on to give as satisfactory results as, or even better results than, some shorter existing ones on the alternate current system, but because it does not appear to me that along the route there is at present sufficient demand for power to justify as large an expenditure of capital as would be compatible with a transmission line 580 miles long as the crow flies, and which would be no less than 745 miles long if made along a railway through Pietersburg and Gwanda, should the missing stretch of railway between these two places ever be constructed.

Those who hold the opposite view will doubtless urge that when the Cataract Construction Company of Niagara acquired in 1890 the right to use 100,000 horse-power, and a further right to use subsequently another 100,000 horse-power, it required an extraordinary belief in the future of electrical engineering to expect that 200,000 horse-power could ever be distributed at a price that could compete with large local steam engines, and they will ask, did not even Mr. George Westinghouse, in 1890, advise Mr. Stetson, the first vice-president of the Cataract Construction Company, that it would only be by compressed air that power could be commercially transmitted from Niagara to Buffalo? And now what is the state of things? Power House No. 1, with ten 5000 horse-power dynamos, has been working for some time, Power House No. 2,* with eleven more 5000 horse-power dynamos, was completed last year. Hence 105,000 horse-power can be developed, and of this 75,000 horse-power is regularly distributed.

Further, the Canadian Niagara Power Company is constructing an electric station of an ultimate capacity of 110,000 horse-power, the Ontario Power Company an electric station, a little lower down, of 200,000 horse-power, and the Toronto Power Company one, a little higher up, of 100,000 horse-power, all these three being on the Canadian side.

Also the Electric and Hydraulic Company, which in 1881 started with a station, on the American side, to supply only 1500 electrical horse-power, has in hand a third station which will bring its plant capacity up to 135,500 electrical horse-power.

Consequently the total electrical horse-power that could be sent out from these various Niagara power houses, when completed, will approach 700,000 horse-power, and represents about 30 per cent. of the water going over the falls at the time of *minimum* flow. But taking into account the further fact that water is already abstracted to feed the Welland Power Canal and the Chicago Drainage Canal, and that other canals are projected, Mr. A. D. Adams has estimated that about 41 per cent. of the minimum flow of Niagara will cease to pass over the falls. In fact, I conclude that *the water that will, in the near future, cease to pass over the Niagara Falls will be nearly five times as large as the total amount passing over the Victoria Falls this month, August.*[1]

The "Thunder of the Waters," the "Cataract of Fearful Height," in America, which have inspired us and our ancestors with reverential awe, may appeal to our descendants as only a vast electric generating station. Very gratifying to us as engineers, extremely distressful to us as lovers of the beautiful.

Now what has caused this vast development in the distribution of power, what is the secret of this extraordinary success? It is that in the immediate neighbourhood of the falls there have grown up works which take some 60,000 horse-power, works which not only want cheap power, but power in an electric form for electro-chemical processes, and need it in an undiminished amount day and night, week-day and Sunday. The Carborundum Company, which manufactures emery's rival grinding material, furnishes an absolutely steady load of 5000 electric horse-power; the Union Carbide Company 15,000, and so on; loads which, from their magnitude and their absolute steadiness, make the electric light engineer's mouth water.

Now what is the prospect of such a steady load growing up locally within, say, 3 miles of your falls? Even

[1] The Resident Commissioner of the Bechuanaland Protectorate, writing to *The Times* from Mafeking the day after the delivery of this lecture, said:—"The volume of water passing over the (Victoria) Falls, was, it is true, infinitely less on August 16, 1905, than on the same date in 1883. It is less to-day than it has ever been in the memory of man."

on the spot it is difficult to obtain trustworthy information; by some it is said that one condition of the contract for the construction of the railway, which is being pushed forward to the copper, lead, and zinc fields at Broken Hill, 400 miles to the north-east, is that 100,000 tons of the ore must be sent to Beira yearly for ten years. If true, then that ore will not be available for reduction at the falls.

There is a convenient spot for a power station near the water at the end of the second gorge—all the Niagara power stations are on the top of the falls, with the exception of those of the Ontario Power Company, and the old Electric and Hydraulic Company—and it is the latter method of construction that would be the most suitable to follow at a Victoria power station.

But jealously guard the beauty of your falls. The protection of the grandeur of their American sister was the underlying idea of Thomas Evershed's hydraulic power scheme of 1886. How little has that object been kept sight of?

Niagara *was* glorious nature, to-day it is power, Victoria is poetry.

FORTHCOMING BOOKS OF SCIENCE.

MR. EDWARD ARNOLD gives notice of:—"The Great Plateau, being an Account of Exploration in Central Tibet, 1903, and of the Gartok Expedition, 1904–1905," by Captain C. G. Rawling, illustrated; "In the Desert," by L. M. Phillipps, illustrated; "Two Years in the Antarctic, being a Narrative of the British National Antarctic Expedition," by Lieut. A. B. Armitage, illustrated; "Common Ailments and their Treatment," by Dr. M. H. Naylor; "Electric Lighting for the Inexperienced," by H. Walter; "Races of Domestic Poultry," by E. Brown, illustrated; "Recent Advances in Physiology," by Drs. A. P. Beddard, L. Hill, F.R.S., J. J. R. Macleod, B. Moore, and M. S. Pembrey; "Valves and Valve Gear Mechanisms," by Prof. W. E. Dalby, illustrated; "Surgical Nursing and the Principles of Surgery for Nurses," by Dr. R. Howard, illustrated; "The Laws of Health," by Dr. D. Nabarro, illustrated; and new editions of "Practical Physiology," by Drs. A. P. Beddard, J. S. Edkins, L. Hill, F.R.S., J. J. R. Macleod, and M. S. Pembrey, illustrated; and "Food and the Principles of Dietetics," by Dr. R. Hutchison, illustrated.

Messrs. Baillière, Tindall and Cox's list includes:—"Psychiatry," by Prof. Bianchi, translated by Dr. J. H. MacDonald; "Manual of Anatomy," by Dr. A. M. Buchanan, illustrated; "Manual of Military Hygiene," by Lieut.-Colonel R. Caldwell, illustrated; "Aids to Surgical Diagnosis," by H. W. Carson; "Sound and Rhythm," by Dr. W. Edmunds, illustrated; "Aids to Pathology," by Dr. W. d'Este Emery; "Trypanosomata and the Trypanosomiases," by A. Laveran and F. Mesnil, translated and edited by Dr. D. Nabarro; "Nodal Fevers," by Dr. A. A. Lendon, illustrated; "Applied Bacteriology," by C. G. Moor and Prof. R. T. Hewlett; "Practical Agricultural Chemistry," by F. Robertson; "Sanitary Science Laboratory Work," by Dr. D. Sommerville, illustrated; and new editions of "Heart Disease, with Special Reference to Prognosis and Treatment," by Sir W. H. Broadbent, Bart., F.R.S., and Dr. J. F. H. Broadbent, illustrated; "Physical Diagnosis," by Dr. R. C. Cabot; "Lectures on Clinical Psychiatry," by Dr. E. Kraepelin, authorised translation revised and edited by Dr. T. Johnstone; "Ambulance Work," by Drs. J. W. and J. Martin; "Manual of the Diseases of the Eye, for Students and Practitioners," by Dr. C. H. May and C. Worth, illustrated; "A Manual of Surgery for Students and Practitioners," by Dr. W. Rose and A. Carless; "The Nature and Treatment of Cancer," by Dr. J. A. Shaw-Mackenzie; "Manual of Physiology, with Practical Exercises," by Dr. G. N. Stewart, illustrated; "The Röntgen Rays in Medical Work," by Dr. D. Walsh, illustrated; and "The Deformities of the Human Foot; with their Treatment," by Drs. W. J. Walsham and W. K. Hughes.

Messrs. George Bell and Sons announce:—"Integral Calculus for Beginners," by A. Lodge; and a new edition of "Elementary Dynamics," by W. M. Baker.

Messrs. A. and C. Black promise:—"Black's Medical Dictionary," by J. D. Comrie, illustrated; "The Practical Angler, or the Art of Trout-fishing more particularly applied to Clear Water," by W. C. Stewart; "A Treatise on Zoology," edited by Dr. E. Ray Lankester, F.R.S., part v., "Mollusca," by Dr. P. Pilseneer; and a new edition of "The System of the Stars," by A. M. Clerke, illustrated.

Messrs. W. Blackwood and Sons direct attention to:—"The Forester, a Practical Treatise on British Forestry and Arboriculture for Landlords, Land Agents, and Foresters," by Dr. J. Nisbet, illustrated; and "Herbart's Psychology and Educational Theory, a General Interpretation through the Philosophy of Leibniz," by Dr. J. Davidson.

The list of the Cambridge University Press contains:—"Tables and Constants to Four Figures, for use in Technical, Physical and Nautical Computation and adapted to the Requirements of Junior Mathematical Students," compiled by the Rev. W. Hall; "The First Book of Euclid's Elements with a commentary, based principally upon that of Proclus Diadochus," by W. B. Frankland; "The Theory of Sets of Points," by Drs. W. H. Young and G. C. Young; "The Elements of Solid Geometry, containing the Principal Theorems relating to Lines and Planes in Space, Polyhedra, the Cylinder, Cone and Sphere," by Dr. C. Davison; "The Collected Mathematical Papers of James Joseph Sylvester, F.R.S.," edited by Dr. H. F. Baker, F.R.S., vol. ii.; "The Fauna and Geography of the Maldive and Laccadive Archipelagoes, being the Account of the Work carried on and of the Collections made by an Expedition during the Years 1899 and 1900 under the Leadership of J. Stanley Gardiner, illustrated; "Reports of the Anthropological Expedition to Torres Straits by the Members of the Expedition," edited by Dr. A. C. Haddon, F.R.S.; "Histological Studies on the Localisation of Cerebral Function," by Dr. A. W. Campbell; "Fossil Plants, a Manual for Students of Botany and Geology," by A. C. Seward, F.R.S., illustrated, vol. ii.; "Trees: a Handbook for Students of Forest Botany," by Prof. H. Marshall Ward, F.R.S., illustrated, vols. iv., v., and vi.; "The Morphology of Plants," by J. C. Willis, illustrated; and "An Introduction to Geology," by Dr. J. E. Marr, F.R.S., illustrated.

Messrs. Cassell and Co., Ltd., announce:—"The Zoological Society of London, a Sketch of its Foundation and Development, and the Story of its Farm, Museum, Gardens, Menagerie, and Library," by H. Scherren, illustrated; "Pictures from Nature," by R. and C. Kearton, with Rembrandt photogravures; "Duval's Artistic Anatomy," edited by Prof. A. M. Paterson, illustrated; "A Manual of Chemistry, Inorganic and Organic, covering the Synopsis of the Conjoint Board and the Society of Apothecaries," by Dr. A. P. Luff and F. J. M. Page, illustrated; "Organotherapy, or Treatment by Means of Preparations of Various Organs," by Dr. T. H. B. Shaw; "Hygiene and Public Health," by Drs. B. A. Whitelegge, C.B., and G. Newman, illustrated; "Clinical Methods, a Guide to the Practical Study of Medicine," by Dr. R. Hutchison and H. Rainy, illustrated; and "Materia Medica and Therapeutics, an Introduction to the Rational Treatment of Disease," by Dr. J. M. Bruce.

The Clarendon Press notices include:—"Schiaparelli's Astronomy in the Old Testament," translated; "The Dawn of Modern Geography," by C. R. Beazley, vol. iii.; "Criminal Responsibility," by Dr. C. Mercier; "Knuth's Flower Pollination," translated by J. R. A. Davis; and "Solereder's Anatomical Characters of the Dicotyledonous Orders," translated by L. A. Boodle and F. E. Fritsch, revised by H. D. Scott.

Messrs. A. Constable and Co., Ltd., will issue:—"The Ways of Nature," by J. Burroughs; "A Study of Aboriginal Life in Australia, the Euahlai Tribe," by Mrs. L. Parker, illustrated; "Two Bird-Lovers in Mexico," by C. W. Beebe, illustrated; "The Fixed Period," five addresses by Prof. W. Osler; "Scarabs, an Introduction to the Study of Egyptian Seals and Signet Rings," by P. E. Newberry, illustrated; "Ethics and Moral Science," by L. Lévy-Bruhl, translated by E. Lee; "The Subconscious, a Study in Descriptive Psychology," by Prof. Jastrow; "Motor Vehicles and

Motors," by W. W. Beaumont, vol. ii., illustrated; "Subaqueous Tunnelling," by W. C. Copperthwaite, illustrated; "The Economic and Commercial Theory of Heat Power Plants," by R. H. Smith; "Electric Railways, Theoretically and Practically Treated," by S. W. Ashe and S. D. Keiley, illustrated; "Modern American Machine Tools," by C. Benjamin, illustrated; "Steam Turbines, with an Appendix on Gas Turbines and the Future of Heat Engines," by Dr. A. Stodola, illustrated; "National Engineering and Trade Lectures," edited by B. H. Morgan: vol. ii., "British Progress in Pumps and Pumping Engines," by P. R. Bjorling; vol. iii., "British Progress in Gas Works Plant and Machinery," by C. E. Brackenbury; "Mechanical Appliances, Mechanical Movements and Novelties of Construction," by G. D. Hiscox, illustrated; "Tropical Diseases," by Sir P. Manson, K.C.M.G., F.R.S., illustrated; "Diets and Dietetics," by A. Gauthier, translated by Dr. Rice-Oxley; "The Bacteriology of Peritonitis," by Dr. L. Dudgeon and P. W. G. Sargent; "Physiology of the Nervous System," by J. P. Morat, translated and edited by Dr. H. W. Syers, illustrated; and "Leprosy and Fish Eating," by Dr. J. Hutchinson, F.R.S., illustrated.

Messrs. J. M. Dent and Co. announce:—"The Bird-watcher in the Shetlands," by E. Selous, illustrated; and "Introduction to Geometry," by Drs. G. C. and W. H. Young.

Messrs. Duckworth and Co. have in hand:—"Handbook of Geography: Physiographical and Mathematical," by Dr. E. Reich, with maps and diagrams; and a new edition of "A Glossary of Botanic Terms, with their Derivation and Accent," by B. D. Jackson.

Mr. A. C. Fifield promises:—"The Science of Symbols," by G. Blount; and "Poverty and Hereditary Genius," by F. C. Constable.

Messrs. R. Friedländer and Son (Berlin) promise:—"Carnephorus im Baikal-See," by A. Korotneff; Tierreich, Lief. 21, "Amphipoda," I., by T. R. R. Stebbing, Lief. 22, "Heliconidæ," by H. Stickel u. H. Riffarth; "Joh. Wislicenus, his Life and Works," by E. Beckmann; "Wissenschaftl. Ergebnisse einer zoolog. Expedition nach dem Baikal-See," Heft. i., ii., v.; and "Plankton des Baikal-Sees," by Zernow.

The Funk and Wagnalls Co. will publish:—"Atonia Gastrica," by Dr. A. Rose; "Carbonic Acid in Medicine," by Dr. A. Rose; "Psychic Treatment of Nervous Disorders," by Dr. Dubois; and "Psycho-Neurosis and its Moral Treatment," by Dr. Dubois.

Mr. Alexander Gardner announces:—"Familiar Scottish Birds," by A. N. Simpson.

Messrs. Gauthier-Villars (Paris) give notice of:—"Sur les Systèmes triplement indéterminés et sur les Systèmes triple-orthogonaux," by Prof. G. Guichard, illustrated; "Œuvres de Charles Hermite," Tomes ii. and iii.; "Cours d'Analyse de la Faculté des Sciences de Paris," by Prof. E. Goursat, Tome ii.: "Théorie des Fonctions analytiques. Équations différentielles. Équations aux Dérivées partielles. Éléments de Calcul des Variations"; "Précis de Photographie générale," by E. Belin, illustrated; "Les Procédés de Commande à Distance au Moyen de l'Electricité," by Frilley; "Les Industries de la Conservation des Aliments," by X. Rocques.

Messrs. Gay and Bird announce:—"The Arab: the Horse of the Future," by Hon. Sir J. Boucaut, K.C.M.G., with a preface by Sir W. Gilbey, Bart., illustrated.

Messrs. Charles Griffin and Co., Ltd., give notice of:—"Mining Law," by C. J. Alford; "Mining Geology: a Text-book for Mining Students and Miners," by Prof. J. Park, illustrated; "Wireless Telegraphy," by Dr. G. Eichhorn, illustrated; "Electricity Meters," by H. G. Solomon, illustrated; "Testing Explosives," by C. E. Bichel and A. Larsen, illustrated; "Paper Technology, an Elementary Manual on the Manufacture, Physical Qualities, Chemical Constituents, and Testing of Paper and Paper-making Fibres, with Selected Tables for the Use of Publishers, Stationers, and Others," by R. W. Sindall, illustrated; "A Practical Laboratory Handbook on the Bacteriology of Brewing," by W. A. Riley; "A Handbook of Medical Jurisprudence and Toxicology, for the Use of Students and Practitioners," by Dr. W. A. Brend, illustrated; "Toxine and Anti-Toxine," by Dr. C. Oppenheimer, translated from the German by C. A. Mitchell; "The Laboratory Book of Mineral Oil Analysis," by J. J. Hicks, illustrated; "Physico-chemical Tables for the Use of Analysts, Physicists, Chemical Manufacturers and Scientific Chemists," vol. ii., "Chemical Physics, Pure and Analytical Chemistry," by J. Castell-Evans; and new editions of "Pétroleum and its Products, a Practical Treatise," by Sir B. Redwood, illustrated; "Gas, Oil, and Air Engines: a Practical Text-book on Internal Combustion Motors," by B. Donkin; "Properties of Matter," by Profs. J. H. Poynting and J. J. Thomson, F.R.S.; and "Principles and Practice of Brewing, for the Use of Students and Practical Men," by W. J. Sykes, illustrated.

Messrs. Harper and Brothers' list includes:—"Evolution: the Master Key," by Dr. C. W. Saleeby; "Practical Electric Wiring," by C. C. Metcalfe; and "Alternating Currents," by Prof. A. Hay.

Mr. W. Heinemann's list contains:—"The World's History, a Survey of Man's Record," edited by Dr. H. F. Helmolt, "Eastern Europe," "The Slavs," "The Teuton and Latin Races," "Western Europe since 1800," "The Atlantic Ocean"; "Through Five Republics, a Critical Description of the Argentine, Brazil, Chile, Uruguay, and Venezuela in 1905," by P. P. Martin, illustrated; "Medicine and the Public," by Dr. S. S. Sprigge; "Concerning Death," by Prof. O. Bloch, edited by Dr. O. Lankester; "Sex and Character," translated from the German of O. Weininger; and "The Dog Book," by J. Watson, 2 vols., illustrated.

Messrs. Hodder and Stoughton will publish:—"With the Abyssinians in Somaliland," by Major J. W. Jenning and Dr. C. Addison; "Woodmyth and Fable," by E. Thompson-Seton; and "The Medical Epitome Series," edited by Dr. V. C. Pedersen, 20 vols.

Messrs. Hutchinson and Co. direct attention to:—"Liberia, the Negro Republic in West Africa," by Sir H. Johnston, G.C.M.G., K.C.B., illustrated; "With Flash-light and Rifle in Equatorial East Africa, a Record of Hunting Adventures and of Studies in Wild Life," by C. G. Schillings, translated by F. Whyte, illustrated.

Messrs. T. C. and E. C. Jack announce:—"The Edinburgh Stereoscopic Atlas of Anatomy," edited by Dr. D. Waterston; "Moths and Butterflies of the United States East of the Rocky Mountains," by S. F. Denton, illustrated; and five volumes by Dr. C. W. Saleeby entitled respectively:—"Evolution," "Heredity," "Psychology," "Ethics," and "Sociology."

Mr. F. Lehmann (Stuttgart) promises:—"Oologia universalis palæarctica," by G. Krause, 150 parts, illustrated.

Messrs. Crosby Lockwood and Son give notice of:—"Motor Vehicles for Business Purposes, a Practical Handbook for Those Interested in the Transport of Passengers and Goods," by A. J. Wallis-Tayler, illustrated; "Milling Machines, a Practical Treatise on their Design, Construction, Equipment and Economic Working, illustrated with Examples of Recent Designs by Leading English, French, and American Engineers," by J. Horner; "The Elementary Principles of Electrical Engineering, a Class-book for Junior and Advanced Students," by J. H. Alexander, illustrated; "The Horticultural Note Book, a Manual of Practical Rules, Data, and Tables, for the Use of Students, Gardeners, Nurserymen, and Others interested in Flower, Fruit and Vegetable Culture, or in the Laying-out and Management of Gardens," by J. C. Newsham; and new editions of "Electricity as Applied to Mining," by A. Lupton, G. D. A. Parr, and H. Perkin, illustrated; and "The Art of Leather Manufacture, a Practical Handbook in which the Operations of Tanning, Currying, and Leather Dressing are fully Described, and the Principles of Tanning Explained, together with a Description of the Arts of Glue Boiling, Gut Dressing, &c.," by A. Watt.

Messrs. Longmans, Green and Co.'s list includes:—"The Mammals of Great Britain and Ireland," by J. G. Millais, vol. iii., illustrated; "The Secret of the Totem," by Andrew Lang; "The Physiology and Therapeutics of the Harrogate Waters, Baths, &c.," by Drs. W. Bain and W. Edgecombe; "The Scientific Principles of Wireless Telegraphy," by Dr. J. A. Fleming, F.R.S.; "Steam

Turbines," by W. Gentsch, translated from the German by A. R. Liddell, illustrated; "The Unit in the Struggle for Existence"; "A Common Humoral Factor of Disease and its Bearing on the Practice of Medicine," by Dr. F. Everard Hare; "A Manual of Diseases of the Nose and its Accessory Cavities," by Dr. H. L. Lack, illustrated; "Synthetica, being Meditations Epistemological and Ontological," by S. S. Laurie; "Wild-fowl," by L. H. De Visme Shaw; "The Fox," by T. F. Dale, illustrated; "Physical Chemistry and its Applications in Medical and Biological Science," by A. Findlay; "Elementary Practical Metallurgy, Iron and Steel," by P. Longmuir, illustrated; "Elementary Electrical Calculations," by W. H. N. James and D. L. Sands; "The Ventilation, Heating, and Lighting of Dwellings," by J. W. Thomas, illustrated; and new editions of "The Diseases of Children, Medical and Surgical," by Dr. H. Ashby and G. A. Wright, illustrated; "Anatomy, Descriptive and Surgical," by H. Gray, F.R.S., edited by T. Pickering Pick and R. Howden, illustrated.

Messrs. Sampson Low, Marston and Co., Ltd., announce:—"From Fibre to Fabric," by E. A. Posselt, being a treatise giving a thorough description of the properties and supply of the fibres, as well as the various processes dealing with wool-cotton, silk, woven and knit goods, illustrated.

Messrs. James Maclehose and Sons (Glasgow) have in the press:—"Kaempfer's History of Japan in 1693; an Account of the State and Government of that Empire; of its Temples and other Buildings; of its Metals, Minerals, Plants and Animals; of the Chronology and Succession of its Emperors;" written in High Dutch, by Engelbert Kaempfer, M.D., Physician to the Dutch Embassy to the Emperor's Court, and translated by J. G. Scheuchzer, F.R.S., 3 vols., illustrated; and "Catalogue of the 'Young' Collection of Books on Chemistry," edited, with bibliographical notes, by Prof. J. Ferguson, 2 vols.

Among Messrs. Macmillan and Co.'s announcements are:—"Lectures on the Early History of the Kingship," by J. G. Frazer; "Tribes of the Malay Peninsula," by W. W. Skeat, 2 vols., illustrated; "A People at School," by H. F. Hall; "Mediæval Rhodesia," by D. Randall-MacIver, illustrated; "The Life-history of British Flowering Plants," by Lord Avebury, F.R.S., illustrated; Cambridge Natural History, vol. i., "Protozoa," by Prof. Marcus Hartog, "Sponges," by Prof. W. J. Sollas, F.R.S., "Jelly-fish, Sea-anemones, &c.," by Prof. S. J. Hickson, F.R.S., "Star-fish, Sea-urchins, &c.," by Prof. E. W. MacBride, illustrated; "Observations of a Naturalist in the Pacific between 1896 and 1899," by Dr. H. B. Guppy, vol. ii., "Plant Dispersal in the Pacific," illustrated; "The Prevention of Senility and a Sanitary Outlook," two addresses, by Sir J. Crichton-Browne, F.R.S.; "Stonehenge Astronomically Considered," by Sir Norman Lockyer, K.C.B., F.R.S., illustrated; "Text-book of Palæontology," by Profs. K. A. Zittell and C. R. Eastman, vol. iii., "Mammalia," illustrated; "The Chemistry of the Proteids," by Dr. Gustav Mann, based on Dr. Cohnheim's "Chemie der Eiweisskörper"; "A Handbook of Climatic Treatment, including Balneology," by Dr. W. R. Huggard; "The Philosophy of Religion," by Prof. H. Höffding, translated by Miss B. E. Meyer; "Idola Theatri: an Explanation of the Fallacious Principles that have hindered the Progress of Philosophy in recent years, further illustrated by Criticisms of some Leading Oxford Thinkers," by H. Sturt; "The Philosophy of Martineau in Relation to the Idealism of the Present Day," by Prof. H. Jones; "Easy Mathematics: chiefly Arithmetic; being a Collection of Hints to Teachers, Parents, self-taught Students, and Adults, and containing a Summary or Indication of most things in Elementary Mathematics useful to be known," by Sir Oliver Lodge, F.R.S.; "A Study in Nursing," by Miss A. L. Pringle; "New Creations in Plant Life, an Authoritative Account of the Life and Work of Luther Burbank," by W. S. Harwood, illustrated; "In the Heart of the Canadian Rockies," by J. Outram, illustrated; "Persia Past and Present, Transcaspia and Turkestan, a Book of Travel and Research," by Prof. A. V. Williams Jackson, illustrated; "Vikings of the Pacific; the Adventures of the Explorers who came from the West, Eastward: Bering, the Dane; the Outlaw Hunters of Russia; Benyousky, the Polish Pirate; Cook and Vancouver, the English Navigators; Gray, of Boston, Discoverer of the Columbia; Drake, Ledyard, and other Soldiers of Fortune on the West Coast of America," by A. C. Laut, illustrated; and new editions of "A System of Medicine," by many writers, edited by Prof. T. Clifford Allbutt, F.R.S., re-edited by Dr. H. D. Rolleston, vol. i.; "A Handbook of Metallurgy," by Prof. Carl Schnabel, translated and edited by Prof. H. Louis, illustrated, vol. i.; and "The Founders of Geology," by Sir Archibald Geikie, F.R.S.

Messrs. Methuen and Co. promise:—"Civil Engineering," by T. C. Fidler, illustrated; "A Junior Magnetism and Electricity," by W. T. Clough, illustrated; "A New Junior Arithmetic," by H. B. Smith; "A New Trigonometry for Beginners," by R. F. D'Arcy; "An Elementary Text-book of Inorganic Chemistry," by R. L. Whiteley; and "Examples in Physics," by C. E. Jackson.

Mr. John Murray announces:—"Researches in Sinai," by Prof. W. F. Petrie, F.R.S., illustrated; "Our Waterways," by U. A. Forbes and W. H. R. Ashford, with map; "Africander Land," by A. R. C. Colquhoun; "The English Flower Gardens and Home Grounds," by W. Robinson, illustrated; "Noteworthy Families (Science), an Index to Kinships in near Degrees between Persons whose Achievements are Honourable, and have been Publickly Recorded," by Dr. F. Galton, F.R.S., and E. Schuster; "Cloud Studies," by A. W. Clayden, illustrated; "The Book of the Rothamsted Experiments," by A. D. Hall, illustrated; "Poultry Farming, some Facts and some Conclusions," by "Home Counties," illustrated; "Creatures of the Night, a Book of Wild Life in Western Britain," by A. W. Rees, illustrated; and "Marine Boilers, their Construction and Working, Dealing more Especially with Tubulous Boilers," based on the first edition of the work by M. L. E. Bertin, second edition brought up to date, edited by L. S. Robertson, illustrated.

Messrs. Nelson and Sons give notice of:—"A Naturalist's Holiday," by E. Step, illustrated.

Messrs. George Newnes, Ltd., will issue:—"What Foods Feed Us?" by E. Miles; and the "Story of the Microscope."

Messrs. C. Arthur Pearson, Ltd., promise:—"The Romance of Mining, containing Interesting Descriptions of the Methods of Mining for Minerals in all Parts of the World," by A. Williams, illustrated; and "The Romance of the Mighty Deep, a Popular Account of the Ocean: the Laws by which it is Ruled, its Wonderful Powers, and Strange Inhabitants," by A. Giberne, illustrated.

Messrs. George Philip and Son, Ltd., announce:—"School Gardening," by W. E. Watkins, illustrated.

Messrs. G. P. Putnam's Sons have in hand:—"Tibet and Turkestan," by O. T. Crosby, illustrated; "The Jordan Valley and Petra," by Drs. W. Libbey and F. E. Hoskins, illustrated; "Diagnosis of Organic Nervous Diseases," by Dr. C. A. Herter, revised by Dr. L. P. Clark, illustrated; and "Physical Regeneration," by J. Cantlie.

The Religious Tract Society direct attention to:—"Home Life in Birdland," by O. G. Pike, illustrated; "Rambles with Nature Students," by Mrs. Brightwen, illustrated; and "A Popular Handbook to the Microscope," by L. Wright.

Messrs. Alston Rivers, Ltd., will issue:—"The Siege of the South Pole," by Dr. H. R. Mill.

Messrs. Rivingtons announce:—"A Three Years' Course of Practical Chemistry," in three parts, by G. H. Martin and E. Jones.

The Walter Scott Publishing Co., Ltd., promise:—"Physical Education, or the Nurture and Management of Children, founded on the Study of their Nature and Constitution," by S. Smiles, edited with additions by Sir H. Beevor, Bart.; and "Diet and Hygiene for Infants," by Dr. F. H. Alderson.

Messrs. Seeley and Co., Ltd., announce:—"The Romance of Modern Mechanism," by A. Williams; and "The Romance of Modern Electricity," by C. R. Gibson, illustrated.

Messrs. Smith, Elder and Co. give notice of "The Source of the Blue Nile, a Record of a Journey through the Soudan to Lake Tsana, in Western Abyssinia, and of the

Return to Egypt by the Valley of the Atbara, with a Note on the Religions, Customs, &c., of Abyssinia," by A. J. Hayes; "Entomological Appendix," by Prof. E. B. Poulton, F.R.S., illustrated; and "Ellis's Demonstrations of Anatomy, being a Guide to the Knowledge of the Human Body by Dissection," edited by Dr. C. Addison, illustrated.

The list of the Society for Promoting Christian Knowledge includes:—a new edition of "Early Britain: Roman Roads in Britain," by T. Codrington.

Messrs. Swan Sonnenschein and Co., Ltd., announce:—"Physiological Psychology," by Prof. W. Wundt, a translation of the fifth and wholly re-written German edition by Prof. E. B. Titchener, in 3 vols., vol. ii., illustrated; "The History of Philosophy," by Dr. J. E. Erdmann, an English abridgment translated and edited by W. S. Hough; "Thoughts and Things: a Genetic Study of Logical Process," by Prof. M. Baldwin, vol. i., "Theory of Knowledge, Functional Logic," vol. ii., "Theory of Reality, Real Logic"; "The Needs of Man: a Book of Suggestions," by Dr. W. W. Hall; "The Student's Text-book of Zoology," by A. Sedgwick, F.R.S., vol. iii., illustrated; "The Student's Hygiene, with Special Reference to the Syllabus of the Board of Education, 1905," by E. Evans, illustrated; "The Chemistry of Common Life, with Special Reference to the Syllabus of the Board of Education, 1905," by J. B. Coppock, illustrated; "School Gardening for Little Children," by L. R. Latter; and a new edition of "Introduction to the Study of Organic Chemistry," by J. Wade, illustrated.

Among the announcements of the University Tutorial Press, Ltd., are:—"The Primary Arithmetic," part ii., (Weights and Measures, Vulgar Fractions, Practice, &c.), part iii.; "Geometry, Theoretical and Practical," by W. P. Workman and A. G. Cracknell, part i.; "Scholarship Geometry," by W. P. Workman and A. G. Cracknell; "Logarithms, and How to Use Them"; "First Stage Chemistry, Theoretical Organic," by Dr. R. A. Lyster; "Junior Chemistry," by R. H. Adie; "Technical Electricity," by Prof. H. T. Davidge and R. W. Hutchinson; "School Magnetism and Electricity," by Dr. R. H. Jude; "First Stage Physiology," by Dr. G. N. Meachen; "Practical Physics," by W. R. Bower and J. Satterly; "Properties of Matter," by C. J. L. Wagstaff; "Elementary Science of Common Life (Chemistry)," subject xxvi. of the Board of Education Science Examinations, by W. T. Boone; "Section One, Biology" (subject xv. of the Board of Education Science Examinations), by W. S. Furneaux; "Section One, Physiography" (subject xxiii. of the Board of Education Science Examinations); "Scholarship Elementary Science—Biology," for section ii.; "Principles and Methods of Education," by Dr. S. S. F. Fletcher and Prof. J. Welton; and new editions of "Chemical Analysis," by Drs. W. Briggs and R. W. Stewart; and "Inorganic Chemistry, Second Stage (Theoretical)," by Dr. G. H. Bailey.

Mr. T. Fisher Unwin gives notice of:—"Sport and Travel in Abyssinia," by Lord Hindlip, illustrated; "Siberia, a Record of Travel, Climbing, and Exploration," by S. Turner, illustrated; "Rambles on the Riviera," by Prof. E. Strasburger, illustrated; "Round About My Peking Garden," by Mrs. A. Little, illustrated; "In Search of El Dorado, a Wanderer's Experiences," by A. Macdonald, illustrated; "Recreations of a Naturalist," by J. E. Harting, illustrated; "The Nature and Origin of Living Matter," by Dr. H. C. Bastian, F.R.S., illustrated; "The Mental Traits of Sex," by H. B. Thompson; "Fishes I Have Known," by A. H. Beavan, illustrated; "The Evolution of the World and of Man," by G. E. Boxall; and "Our School Out-of-Doors," by the Hon. M. C. Leigh, illustrated.

Messrs. Whittaker and Co. promise:—"Steam Turbine Engineering," by H. M. Hobart and T. Stevens; "Wireless Telegraphy and Telephony," by D. Mazzotto, translated by S. R. Bottone; "A Pocket Book of Aëronautics," by H. W. L. Moedebeck, translated by Dr. W. M. Varley; "Armature Construction," by H. M. Hobart; "Electric Welding," by F. J. Wallis-Jones; "Electricity in Mines," by P. R. Allen; "Single-phase Commutator Motors," by F. Punga and R. F. Looser; "Household Applications of Electricity," by S. R. Bottone; "A Text-book of Botany," by M. Yates, part i., "The Anatomy of Flowering Plants"; and new editions of "Electricity in its Applications to Telegraphy," by T. E. Herbert; "The Alternating Current Circuit and Motor," by W. P. Maycock; "Whittaker's Electrical Engineers' Pocket Book," edited by K. Edgcumbe; "Central Station Electricity Supply," by A. Gay and C. H. Yeaman; "The Management of Accumulators," by Sir D. Salomons, Bart.; "The Practical Telephone Handbook," by J. Poole; "Radiography and the X-Rays," by S. R. Bottone; and "Dissections Illustrated," by C. Brodie.

Messrs. Williams and Norgate announce:—"The Evolution of Religion, an Anthropological Study," by Dr. L. R. Farnell; "Life and Matter, a Criticism of Prof. Haeckel's 'Riddle of the Universe,'" by Sir Oliver Lodge, F.R.S.; and "The Inflammation Idea in General Pathology," by Dr. W. H. Ransom, F.R.S.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—The Indian forestry probationers elected last August have come into residence, and the India Office has issued a notice that thirteen more probationers will be selected at the end of October. Candidates must have passed Responsions at Oxford or the previous examination at Cambridge, or some equivalent examination, and will be expected to have some knowledge of chemistry, physics and mechanics, and to be between the age of eighteen and twenty-one years, but the selection board will have the power to relax the superior age limit in the case of candidates who have taken a university degree. Names of intending candidates must be sent to the Under-Secretary of State for India not later than October 26; forms of application can be obtained from Dr. Schlich, 29 Banbury Road, Oxford.

CAMBRIDGE.—The syndicate appointed to consider the desirability of establishing in the university a diploma in forestry is of opinion (1) that a diploma in forestry should be established; (2) that forestry should form the principal subject of the final examination for the diploma; (3) that the diploma should be granted only to graduates of the university; (4) that candidates for the diploma should show evidence of having resided for the equivalent of one year in some recognised centre of instruction in practical forestry. If these recommendations be approved by the senate, the syndicate proposes to draw up and submit to that body detailed regulations for the scope and conduct of the proposed examinations and for the courses of lectures and practical instruction to be required of candidates for the diploma.

At Emmanuel College a studentship of the value of 150*l.* is offered for the encouragement of research in any branch of study recognised by the university. The studentship is open to graduate members of the university whose age does not exceed twenty-eight on January 1, 1906. It is tenable in the first instance for one year from January 1, 1906, but the student may be re-elected for a second period of one year. The latest date for receiving applications is November 20. Further information may be obtained from the master. The student elected is not required to become a member of Emmanuel College.

Mr. J. L. Tuckett, of Trinity College, has been appointed senior demonstrator of physiology until September 29, 1908, and Mr. S. W. Cole, of the same college, will succeed Mr. Tuckett as additional demonstrator in the same subject. Dr. H. B. Roderick, of Emmanuel College, has been re-appointed demonstrator of surgery. Prof. Hopkinson has been elected to represent the board of physics and chemistry on the general board of studies. Mr. J. J. Lister has been re-elected demonstrator of comparative anatomy.

MR. JAMES MILLIKAN, who has given 180,000*l.* for the establishment of a university at Decatur, Ill., which shall bear his name, has offered, we learn from *Science*, to give a further 200,000*l.* to the institution.

A COMMITTEE has been appointed to inquire into the expenditure on public education in England and Wales from Exchequer grants, local rates, and other sources, with the view of ascertaining the various causes for the

existing diversity in the amount of rate levied for education by local authorities, and the varying relation which this amount bears to the total local rates in each area. All the members of the committee are officially connected with the Civil Service.

THE London County Council School of Marine Engineering in High Street, Poplar, has been established to enable

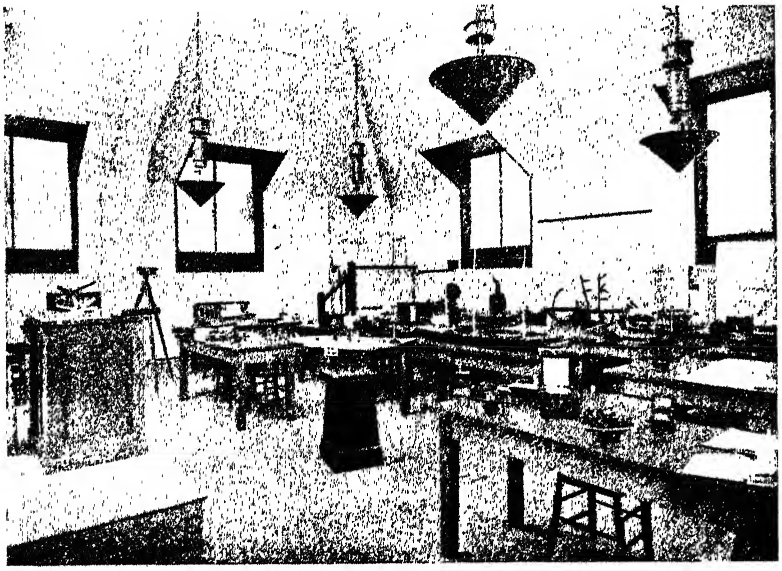

FIG. 1.—Navigation Room of the London County Council School of Marine Engineering, Poplar.

persons in the engineering and shipping industries of the Poplar and neighbouring districts to acquire an intimate knowledge of the principles which underlie the work on which they are engaged, instruction being given in physics, chemistry, and mathematics, as well as in the more practical subjects dealt with in the drawing offices, chart room, and engineering laboratories and workshops. The nautical day school is equipped with modern nautical instruments and seamanship models, and a portion of the roof of the building is arranged so as to form an observing terrace for meteorological and astronomical observations. Provision is also made for the thorough teaching of the principles of electrical engineering, and in the chemical laboratories students have opportunities of making investigations in connection with the calorific value of fuels, methods of purifying feed waters, and other subjects. The accompanying illustration shows the navigation room of the school.

PROF. R. MELDOLA, F.R.S., distributed, on October 11, the prizes and certificates gained during the session 1904–5 by the students of Herold's Institute, the London School of Leather Manufacture. The report of the director of the school, Dr. J. Gordon Parker, was read at the meeting, and showed that during the year a large amount of research work has been done, and the staff of the institute has contributed in no small degree to the important investigation connected with the deterioration of bookbinding leather carried out by the Society of Arts committee on bookbinding leather. Prof. Meldola, replying to a vote of thanks, reminded those present that in other countries there is a direct relationship between technical institutions and the industries. In this country, unfortunately, there is too often indifference or open hostility. Manufacturers have suffered through their unwillingness to modify old procedure and to face new sets of conditions, but it is gratifying to know that hostility to technical instruction is being overcome.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, May 11.—"On the Cytology of Apogamy and Apospory. —II. Preliminary Note on Apospory." By Miss L. **Digby.** Communicated by Prof. J. B. Farmer, F.R.S.

Apospory is the direct vegetative process which leads from the sporophyte to the gametophyte without the intervention of spores.

The fronds of *Nephrodium pseudo-mas*, Rich., var. *cristata apospora*, Druery, were layered in pans of earth, and soon showed aposporal growth. This arises from the surface and edge of the pinnule, and assumes prothalloid characters. These prothalli have no cushion; the embryo is a vegetative outgrowth.

The nuclear divisions of prothallus and embryo have been studied, and the calculated number of chromosomes is forty-three and forty-one respectively (see Fig.). This approximation undoubtedly proves that there is *no reduction* during the transition from the sporophyte to the gametophyte. A similar result has been obtained in *Athyrium Filix-faemina*, var. *clarissima*, Jones.

The apogamous prothalli of *Nephrodium pseudo-mas*

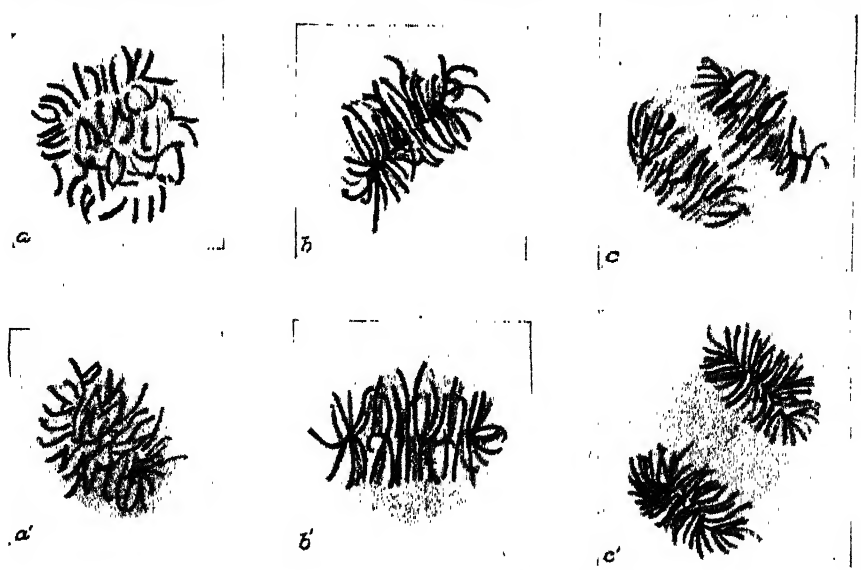

FIG. 1.—Diagrams of nuclear divisions. *a b c* in prothallus. *a' b' c'* in embryo.

cristata apospora show no nuclear migration, whereas about 73 per cent. of those of *Nephrodium pseudo-mas*, Rich., var. *polydactyla*, Wills,[1] exhibit this phenomenon. This is easily explained. Whereas in the former the nuclei of the aposporously developed prothalli have already the full complement of somatic chromosomes, in the latter

they have only half the number, as the prothalli germinate from spores, the origin of which undoubtedly involves a reduction. Hence the sporophytic number in that case is regained by migration and subsequent fusion of two prothallial nuclei.

MANCHESTER.

Literary and Philosophical Society, October 3.—Sir William H. Bailey, president, in the chair.—Note on the buccal pits of peripatus: C. G. **Hewitt.** A general outline of the characters of peripatus was given. Recently, tracheal structures had been described in an Australian species, *Ooperipatus oviparus,* in connection with the buccal pits. These pits are formed by the hollowing out of the long, chitinous levers which are attached to the inner pair of jaws; they are continuous with the cavity of the mouth. The paper embodied the results of an investigation into the nature of these buccal pits in *Ooperipatus oviparus* and two other species. It was found that tracheæ do not occur in this region of the body, and that the striated muscle fibres which work the jaw-levers had been mistaken for tracheæ.

PARIS.

Academy of Sciences, October 9.—M. Troost in the chair.—The president announced the death of Prof. Baron de Richthofen, correspondant in the section of mineralogy.—Observation of the total eclipse of the sun of August 30 at Alcosebre (Spain): J. **Janssen.** Just before totality the sky was not absolutely clear, a few light clouds interfering somewhat with the photography of the phases, but some minutes before totality the clouds disappeared, and the whole period of totality was studied under the best conditions. Three good photographs of the corona were obtained by M. Pasteur, M. Millochau was able to obtain photographs of the spectrum of the reversing layer and of the corona, and M. Stefanik made ocular observations on the green ray of the corona and of the extreme red. Numerous photographs of the phases were obtained.—On the creation of an international association for solar studies: J. **Janssen.** A *résumé* of the principal resolutions passed at the recent meeting at Oxford.—On the first volume of the "Catalogue photographique du Ciel," published by the Observatory of Bordeaux: M. **Lœwy.** This catalogue contains the rectilinear coordinates of 49,772 stars relating to a zone comprised between +16° and +18° declination. Details of the methods adopted are given, and a special study of the errors has been made.—On the earthquake felt at Stromboli on September 8, and on the present state of the volcano: A. **Lacroix.** The earthquake of September 8, which caused such disasters in Calabria, was also severely felt at Stromboli, as, although no fatalities resulted in the island, there was hardly a building which remained undamaged. Numerous crevasses appeared, some a metre wide and 20 metres long. Some observations were made on the volcano in eruption at a distance of 150 metres from the crater, special attention being given to the times elapsing between the explosions. It would appear that the more violent explosions are not separated from those preceding by an interval of time specially long.—Observation of the total eclipse of the sun, August 30, made at Guelma, Algeria: E. **Stephan.** The work attempted was limited to direct visual observations, which were carried out under excellent atmospheric conditions.—Spectroscopic researches made during the eclipse of the sun, August 30, at Alcosebre (Spain): Milan **Stefanik.** Details of visual observations are given.—On the observation of the total eclipse of August 30, made at Alcosebre (Spain): G. **Millochau.** The scheme of work proposed included the photographic study of the spectra of the reversing layer and the chromosphere in the luminous region, especially in the red, yellow, and green; the spectrum of the corona in the same region; similar researches in the ultra-violet; photographs during totality with plates sensible to the red rays, utilising a red screen to cut off other radiations. Details of the instruments are given, the full discussion of the results being reserved for a later paper.—On the polarised light of the solar corona: J. J. **Landerer.**—Mathematical groups containing several operations of the second order: G. A. **Miller.**—On some derivatives of cyclohexane: P. **Freundler** and E. **Damond.** The starting point of this work was cyclohexanol, prepared by Sabatier and Senderens' method. This was converted into the monobromo- and monoiodo-derivatives by the action of phosphorus bromide and iodide, and rectifying under reduced pressure. These compounds do not, as a rule, give good yields in condensation with sodium derivatives, an exception being in the reaction with sodiomalonic ester, the yield in this case being 27 per cent.—On the decomposition of meta- and para-nitrobenzylic alcohols under the influence of aqueous and alcoholic soda: P. **Carré.**—On some phenolic ethers with the pseudo-allyl chain $ArC(CH_3)=CH_2$: MM. **Béhal** and **Tiffeneau.**—On sambunigrin, a new hydrocyanic glucoside extracted from the leaves of the black elder: Em. **Bourquelot** and Em. **Danjou.** The existence of this glucoside has been indicated in a previous note, and in the present communication details are given of the method by which the sambunigrin has been obtained in a pure state. The new glucoside appears to be isomeric with the amygdonitrile glucoside of Fischer, from which it differs in its rotatory power.—Statistical researches on the evolution of the size of plants: Mlle. **Stefanowska.** The results are expressed in the form of curves.—Study of the blood in the case of a "bleeder": P. Émile **Weil.** Numerous experiments have been made on the coagulation of the blood from this case. The most important result obtained was the observation that the anomalous coagulation in these cases is not due to the presence of any anti-coagulating substances in the blood, but arises from the absence or alteration of certain normal substances, probably the coagulating ferment. It is sufficient to add traces of normal serum to cause a normal coagulation.—On the direct proofs of the existence of counter trade winds: Lawrence **Rotch** and Léon Teisserenc **de Bort.**

THE STUDY OF FISHES.

A Guide to the Study of Fishes. By David Starr Jordan. Vol. i., pp. xxvi+623; vol. ii., pp. xxii+599; with coloured frontispieces and 427 illustrations. (New York: H. Holt and Co., 1905.) Price 40s.

THIS beautiful work naturally invites comparison with the recently published seventh volume of the "Cambridge Natural History." Both actually cover the same ground, since both contain also an account of those invertebrates which, like Balanoglossus, Tunicates, and Amphioxus, claim the ambitious honour of a more or less direct ancestral position to the fishes.

It has been objected that the anatomical treatment, although good, exact, and up to date, takes too much space of the Cambridge volume, to the detriment of those more œcological questions which are of more general interest, and are, after all, as important as the structural detail, because they make up the life of the fish. The systematic account of the Teleostei, containing Boulenger's new classification, forms the main feature, rather stern, only here and there relieved by some interesting and little known information about habits, showing that want of space, not disinclination, has guided the author.

The author, who is president of the young and vigorous University at Palo Alto, in beautiful and exhilarating California, proceeds nominally upon the same plan, but its execution is totally different. With him the fish is alive, even the fossil. Having travelled much, he has fished with the Japanese, trawled in the vast Pacific, and the huge continent of North America is his special domain. He has collected much, and has observed more "in the good company of the woods and brooks."

"The man who kills all the trout he can, to boast of his skill or fortune, is technically known as a trout-hog. Ethically it is better to lie about your great catches of fine fishes than to make them. For most anglers, also, it is more easy."

The first volume begins with a popular account of the life of the long-eared sunfish. What is a fish? What is it like, and so unlike, to everything else? How does it breathe, see, move, adapt its coloration, and how does it breed? After we have caught it, and observed it in an aquarium, it is dissected, and the student is introduced to the morphology from a general point of view. The account which follows is neither stiff nor anything like exhaustive, but in about 100 pages enough is said to help the intending ichthyologist to an appreciation of the taxonomic importance of ichthyotomy and its salient problems. Many of our fundamental questions of vertebrate morphology find their solution in the fishes. The author devotes a whole and long chapter to the morphology of the fins, with a clear exposition of the vexed controversy whether the pectoral limb has arisen from a problematic lateral skin fold or from an organ like a gillarch, which already did exist, and required but a slight change of shape and function. The organs of respiration lead to a summary of the present state of our knowledge concerning air-bladder and lungs; the other organic systems follow suit. What the author has to tell us are all points which, although they can be studied elsewhere, could not well be omitted from such a work.

Not so chapters x. to xx. Postembryonic development, with the often most peculiar larval forms; instincts, habits and adaptations afford a rich field of observation, graphically described, with admirable illustrations. Witness the photograph of the tens of thousands of fishes which, having run up-stream to spawn after a rain, are left stranded by the falling water.

Protection by the spines, by the poisonous nature of the flesh, electric batteries, luminous organs, quaint nursing habits, are, of course, the stock in trade of any book on fishes. The angling apparatus of Lophius is such a feature, but it is not often that it is treated as follows:—

"In the large group of angler-fishes the first spine of the dorsal fin is modified into a sort of bait to attract smaller fishes into the spacious mouth below. This structure is typical in Lophius, where the fleshy tip of this spine hangs over the great mouth, the huge fish lying at the bottom apparently inanimate as a stone. In other related fishes this spine has different forms, being often reduced to a vestige, of little value as a lure, but retained in accordance with the law of heredity. In a deep-sea angler the bait is enlarged, provided with fleshy streamers and a luminous body which serves to attract small fishes in the depths. The forms and uses of this spine in this group constitute a very suggestive chapter in the study of specialisation and ultimate degradation, when the typical function is not needed or becomes ineffective."

This is truly observation and reflection combined, and the rendering of it is that of a thorough evolutionist who is in sympathy with his favourite class of creatures.

The colour of fishes is another fertile field, with sexual, nuptial, and protective changes. Perhaps in order to curb the ardour of those who see some special good or purpose in every pattern or colour, we are told that the brilliantly coloured fishes of the tropical coral reefs have no need of protective coloration.

The chapters on geographical distribution might well form an essay by themselves, since in them are interwoven lessons of natural selection, the effects of temperature, agencies of oceanic currents, the effects of the direction of coast-lines, and last, not least, the separation of faunas by isthmus barriers, notably those of Suez and Panama. Their far-reaching results are explained by an analysis of the Japanese fish-fauna in comparison with that of the Mediterranean and Central American waters. But whilst the methods of marine distribution and their final results are relatively simple, the fresh-water fishes provide stiffer problems, and some forty pages are therefore devoted to the ways and means, successes and failures, as exemplified in detail by the fauna of the North American continent. This makes fine and admirable reading, but it also shows the value, scien-

tific and practical, of well directed boards and commissions of agriculture and fisheries.

A long chapter on the history of ichthyology, enlivened by the photographic reproductions of several dozen of the more prominent workers in this field, and a chapter on the evolution of fishes since Ordovician times, bring us to the systematic part, which comprises the last quarter of the first and the whole of the second volume.

Here we have to find fault. There is no thorough classification or system. The table of contents of the chapters makes matters only worse. A single page with an outline of the arrangement would be a boon. The author is well aware of the uncertainty of the position of many of the groups, or of their claim to being natural assemblies at all. He never fails to point out how they may be supposed to be connected with each other, or that they are side branches of the ideal tree, but he too often assigns to his groups values or rank without reference to the next higher category of which they are meant to form part. The result of this treatment is bewildering to the reader unless he studies the whole work and abstracts from the many hints given a system of his own; and in this respect the book is truly a "Guide to the Study of Fishes," and not a categorical text-book.

The terms subclass, series, order, subdivision, are often used promiscuously, sometimes as a heading which differs in its meaning from that assigned to it further on.

This being a case of fault-finding, a matter of regret with a work which is otherwise so well done, so full of information, and opening out so many new vistas, let the reader try whether he can abstract from it a co- and sub-ordinated systematic arrangement.

However, perhaps the author did not intend to give a rounded-off classification. In many respects his views differ from Boulenger's system, and it may well be asked whether there is a single class of animals about the grouping of which there is general consensus. Leaving, therefore, this point, we cannot but admire the masterly manner in which the enormous class of fishes, recent and extinct, has been marshalled. Group after group is diagnosed, reviewed, discussed, figured, and endowed with never flagging interest.

"And with these dainty freaks of the sea, the result of centuries of centuries of specialisation, degeneration and adaptation, we close the long roll-call of the fishes." H. G.

THE FAR EAST.

The Far East. By Archibald Little. Pp. viii+334. (London: Frowde, 1905.) Price 7s. 6d.

OF late years the Far East is only far in actual distance; it is very near to our thoughts, while the ignorance regarding these lands is being very rapidly dispelled. At the present moment it is Japan that is attracting our attention; five years ago it was China, and probably in a few more years, now that the Russo-Japanese contest is concluded, China will again be the centre of interest. In his most interesting book, "The Far East," Mr. Archibald Little devotes more space to China than to Japan, having been himself for very many years a resident of the former country, and possessing a knowledge of the Chinese surpassed by no one. China stands now at the parting of the ways; for many years resolute in keeping out foreign inventions so distasteful to the old-fashioned mandarin, circumstances have proved too strong, and railways, the precursors of western life, are now being built or projected throughout the land. No one can foresee what changes twenty years will bring about in this vast country, a vastness which Mr. Little brings home to us by his diagrams and comparative tables.

To a lover of things historical, nothing can be more fascinating than to wander back through the long centuries to some thousands of years before the Christian era; and this it is necessary to do if one would study Chinese history. To compress this into a volume of reasonable size and yet to give a comprehensive account of each province is a difficult task, but Mr. Little's apology in his preface is unnecessary.

China naturally lends itself to the division, which is carried out in this book, into the northern, middle, and southern basins, with the four dependencies of Manchuria, Mongolia, Turkestan, and Tibet. Of these four dependencies, it is in Mongolia and Turkestan only that Chinese rule may be considered as firmly established; in Tibet the amount of power in the hands of the Chinese depends on the personal characteristics of the Tibetan Dalai Lama and Regent and the Chinese Amban; undoubtedly one result of Younghusband's mission to Lhasa has been to emphasise Chinese authority in the eyes of the Tibetans. Of Manchuria at the present moment it is unsafe to hazard an opinion, but everything points to its becoming once more a Chinese possession under possibly Japanese moral tutelage. A consideration of the two chapters on "Whilom Dependencies" leads naturally to a thought of how of late years the more outlying dependencies have been gradually lopped off, how the once mighty Chinese Empire has degenerated. Cochin China, Annam, Corea, as well as Burma (which does not enter into the scope of this book), all once paid tribute to China.

Siam, for many years in danger of being squeezed out of existence between two European Powers, has taken a new lease of life, and is now in a more prosperous condition than it has been for many years.

Japan might have many chapters written about it, but we have been lately so inundated with things Japanese that it is almost with a feeling of relief that we turn once more to the chapters on China itself. We would, in truth, most warmly recommend this book to anyone about to travel in the Far East, as well as to the stay-at-home reader, more particularly as regards China.

Take the northern basin. What more interesting to read about than Peking itself; Shansi, the province of coal and iron; Shantung, where the Germans at great cost are slowly developing their trade through Kiao Chau? What great river in the world has

changed its course as the Yellow River has? What other country in the world has built a Great Wall? We are accustomed to hear much of the peculation of the officials, but Mr. Little does not emphasise this; in many districts the officials are revered and beloved by the people.

Consider the Yangtse Valley, again, where ocean steamers can reach Hankow, where steamers with Mr. Little himself as their pioneer have reached to Chung King, and lately still further. This magnificent river will undoubtedly remain the great high road for commerce into Central China; but railways are and will be built to act as feeders to the main line, much to the profit of the shareholders and of the inhabitants, for Chinese are born traders, and already make use of the pioneer of Chinese railways—the line from Tientsin to Peking—in large numbers.

Finally, we have a vivid description of the southern basin, Canton, Hong Kong, and the provinces bordering on French territory. Yunnan, which adjoins our Burma, has a particular interest to Englishmen; but here, owing to our supineness in days gone by, we have allowed the French to get ahead of us with their railway, which will undoubtedly draw to itself all that is valuable of the trade of the province.

There was a time when many people thought that China would be divided among the Great Powers—that notion is exploded; then came that of spheres of influence—but we have seen this idea also put aside; the policy of the "open door" is all that remains.

We congratulate Mr. Little on having given us a most readable volume, full of information, and yet with that local colouring which is an essential for a book to command the attention of the general reading public.

ABSORPTION SPECTRA.

Handbuch der Spectroscopie. By Prof. H. Kayser. Vol. iii. Pp. viii+604. (Leipzig: S. Hirzel, 1905.)

WHEN Prof. Kayser published the first volume of his "Handbuch der Spectroscopie," he said that the third volume would be devoted to absorption spectra and cognate phenomena. He has, however, found it necessary to treat the subject in two volumes, the first of which contains the methods of investigation of absorption spectra, the variability of absorption, the connection between absorption and chemical constitution, and, finally, a list of all the measurements of the absorption spectra of inorganic and artificial organic substances. In the next volume the absorption of the natural colouring matters in the animal and vegetable kingdom will be described, together with the relation of dispersion and fluorescence to absorption and, lastly, phosphorescence. The present volume is peculiarly interesting, as it deals to a great extent with the application of spectroscopy to chemical and physicochemical problems.

In the first chapter Prof. Kayser deals with the apparatus and methods of investigation of absorption, and includes a discussion upon the nature and laws of absorption. It is well known that considerable confusion exists with regard to the terms used by various experimenters, as, for example, absorption-coefficient, &c. Not the least important section of this chapter is that in which the author discusses these and proposes a uniform set of definitions upon a proper physical basis. In the discussion of the nature of absorption, Prof. Kayser is perhaps a little obscure. He very properly divides absorption into two kinds, namely, the ordinary kind for which Kirchhoff's law holds, and the so-called metallic reflection for which the law does not hold. On p. 9 Prof. Kayser says, in referring to those bodies which show surface colour, *i.e.* metallic reflection, that these bodies show well-marked absorption bands, and that the particular rays are wanting in the transmitted light, not so much because they are strongly absorbed, but because they are strongly reflected. This statement is rather misleading. The phenomenon of metallic reflection is shown by two classes of bodies, firstly, the metals which are perfect conductors, and, secondly, those substances which show surface colour and are not conductors, as, for example, the aniline dyes. Prof. Kayser's remarks, strictly speaking, only apply to the first group, *i.e.* the metals, because as these bodies are conductors the light cannot penetrate below the surface. In the case of the substances belonging to the second group the mechanism must be somewhat different. When a moderately dilute solution of an aniline dye, such as rosaniline, is examined by transmitted light, a very strong absorption band is developed in the green. No surface colour is visible, and undoubtedly the disappearance of the green rays is due to the absorption of these rays by the molecules of the dye. On the theory of resonance, the dye molecules vibrate in sympathy with the green rays and scatter the incident energy. If now the solution is concentrated, the absorption on the surface becomes greater, that is to say, the number of resonating molecules in the surface is increased, until eventually the scattering of the light becomes visible, and we have the surface colour of the same wave-length as the absorption band. It is not accurate to say that the light is reflected rather than absorbed, because in dilute solutions the rays penetrate to a considerable distance before being absorbed.

In the second chapter Prof. Kayser deals with the variation in the absorption spectra of substances with variation in the external conditions. Here he points out that the extraordinary changes undergone by absorbing substances with changes in the solvent, dilution, &c., show clearly what a mass of useless work on absorption spectra has been published owing to the observations having been made under very limited conditions. The most interesting section of this chapter is that in which the variations of the absorption spectra of coloured metallic salts with dilution change are discussed. A great many observations have been made by Ostwald and others upon the absorption of coloured salts and the results published in support of the ionic theory. Unfortunately, more recent experiments have shown that the absorption by the different salts of the same metal and that by the different salts of the same acid show small

but perfectly regular differences. The position of the absorption bands varies with the mass of the colourless ion, and certain other facts have been observed of the same character. Prof. Kayser reviews most carefully the whole of the evidence of absorption spectra that has been brought forward both for and against the ionic hypothesis; he finally concludes that Ostwald's theory, namely, that the behaviour of dilute aqueous solutions of coloured metallic salts is due to the colour of the ions, is untenable. Such an authoritative statement, based on experimental evidence, is very striking and worthy of careful consideration by physical chemists.

The third chapter has been written by Prof. Hartley, and deals with the relation between absorption and chemical constitution. It contains an excellent *résumé* of all the work which has been carried out, chiefly by Prof. Hartley himself, on the bearing of ultra-violet absorption to molecular structure. The value of this work is too well known to need emphasising here, and it is not too much to say that this is one of the most important branches of spectroscopy, and one that is certain to lead to results of far-reaching importance in organic chemistry.

The two last chapters deal in detail with absorption spectra; in the fourth chapter are described the spectra of many substances, selected either because they are of some practical use, or because they possess some special point of interest, while the fifth and last chapter contains an alphabetical list of all substances the absorption of which has been measured.

Of the great value of this book it is impossible to speak too highly; it is sufficient to say that it will rank as the standard work upon absorption. All who read it will appreciate to the full the great care Prof. Kayser has bestowed upon it and the immense labour involved in dealing with the mass of literature upon the subject.

E. C. C. B.

OUR BOOK SHELF.

Identification por las Impresiones digito-palmares (La Dactiloscopia). By Dr. Alberto Yvert. Pp. 111. (La Plata: A. Gasperini, 1905.)

THIS work is the thesis presented by the author to the University of Lyons in order to obtain a doctor's degree in medicine. It deals, firstly, with the uses to which identification by means of finger-prints can be put by the detective, and shows how the fingers of the murderer leave their impression printed in the blood of his victim; while those of the burglar may be brought to light on the window through which he has passed, by the simple expedient of breathing on it, and may be indelibly recorded by means of hydrofluoric acid; and, lastly, the finger-marks of the forger may be revealed on the cheque which he has forged, by means of Mr. Forgeot's method. This last record is produced, first, by the sweat of the fingers that rest on the paper, which, when it evaporates, leaves an invisible print behind it in the salts which were contained in it. This may be made to appear by the application of an 8 per cent. solution of nitrate of platinum, which is affected by these salts in such a way that it blackens when exposed to light.

The author proceeds subsequently to the most important part of his work—a summary of the principal methods of classification of finger-prints. He commences with a somewhat inadequate description of the original system, which, as is well known, is that of Francis Galton; he then goes on to treat with much fuller detail some of the various systems which are based on it. Among these are included that of M. E. K. Henry, which has been adopted by M. Windt, chief of the Identification Service of the Police in Vienna; that of M. Pottecher, chief of the Immigration and Identification Service in Saigon; and of Señor Vucetich, director of the Identification Service in La Plata. It is the last system which is preferred by the author. It consists in dividing all finger-prints into four types, which he names as follows:—(1) *Arco* = arch; (2) *Presilla interna* = internal loop; (3) *Presilla externa* = external loop; (4) *Verticilo* or *Torbellino* = spiral. These terms are descriptive of the figures formed by the lines situated near the centre of the palmar surface of the distal phalanx of each digit. As all ten fingers are taken into account in the classification, and as each may be of any of the above four types, there are 4^{10} (= 1,048,576) classes defined in this way. The minute details of the arrangement enable one to distinguish between different members of the same class.

The pamphlet concludes with a useful bibliography.

E. H. J. S.

Science in South Africa: a Handbook and Review. Prepared under the auspices of the South African Governments and the South African Association for the Advancement of Science. Edited by the Rev. W. Flint and J. D. F. Gilchrist. Pp. x+489. (Cape Town, Pretoria, and Bulawayo: T. Maskew Miller, 1905.)

THOSE members of the British Association who were fortunate enough to visit South Africa this year cannot fail to have benefited by this useful and handsome volume. To those who were unable to accompany the association, but who take an interest in scientific work in South Africa, this "index book" will be a great boon. Of late years, South African scientific literature has increased at a great rate, but the material frequently lies scattered in numerous publications often difficult of access, while so many divergent opinions on the same subject have been expressed that the student is apt to be bewildered. From the present volume the *status quo* of scientific research in South Africa can be ascertained. A long-felt want is thus supplied, and if the scientific literature is to increase at the same rate in the future as it has in the immediate past, a year-book on similar lines would be of inestimable value.

The cost of publication of the present volume has been defrayed by the various South African Governments. In doing this they betray an enlightened policy, for there can be no question that it will direct attention to the vital importance of scientific knowledge in a country so vicariously treated by nature as South Africa, where the natural products are distributed in such a way that they can only be utilised by the application of the discoveries of modern science. To those so trained, South Africa becomes a land of fertile promise.

The present volume is arranged in eight sections, dealing with physical, anthropological, zoological, botanical, geological, mineralogical, economic, educational, and historical problems. The sections and subsections are the voluntary contributions of actual workers, to whom the editors have allowed considerable latitude as to the method of treatment. In some cases the subjects are dealt with historically, in others from the practical point of view. The volume contains numerous illustrations, among which

the handsome coloured plates of blue ground and diamonds of various shapes and colours, presented by Mr. Gardner Williams, stand out conspicuously.

While it is evident that much has been achieved, it is equally certain that in some branches only a start has been made. In fact, the dominant feeling produced by reading the several interesting articles is one that should inspire the greatest hope and enthusiasm among scientific students in this country and throughout South Africa. Here lie new worlds of unknown possibilities. As yet we stand only on the threshold. Far off glimpses of a wonderful country have been obtained, but it is the sight of a Kilimanjaro enshrouded in mist, not of the unclouded mighty mountain-mass. W. G.

Stone Gardens. By Rose Haig Thomas. Pp. xii and plates. (London: Simpkin, Marshall, Hamilton, Kent and Co., Ltd., 1905.)

AN old wall sheltering such plants as are accommodating enough to grow in such a situation is often a delight; but to undertake the formation of a "stone-garden" in the way suggested by the author is to run counter to all our notions of the amenity and purpose of a garden. Various "designs" are offered for adoption, such as a lyre-shaped outline made of paving stones with flower-beds representing the strings, and separated by narrow strips of stone.

Another design shows three snakes intertwined, each snake made of flat stones of a different tint from its neighbour. The spaces between the serpentine convolutions are filled in with flower-beds. Other designs are more appropriate to a formal or architectural garden.

Of course, there is no disputing upon points of taste, and each garden-lover must exercise his or her fancies according to circumstances and in obedience to individual proclivity. But if the designer intends to furnish a model for other people to adopt, then we expect there will be comparatively few garden-lovers who will share the author's taste or feel inclined to adopt her suggestions.

Be this as it may, the author gives very clear directions as to how her designs should be carried out, and very judicious instructions as to the plants to be selected and the method of planting them. Provided these be properly carried out, kindly nature will do her best to conceal the flags and stones, and if the author's designs are somewhat interfered with in the process, that will not be a matter for regret on the part of most garden-lovers. The work is in quarto, with fourteen designs in colour.

Oblique and Isometric Projection. By John Watson. Pp. iv+59. (London: Edward Arnold, n.d.) Price 3s. 6d.

IN defining the forms and dimensions of solids by means of scale drawings, a very useful method in certain cases is that of metric projection whereby three systems of parallel edges of the solid are represented on paper by lines parallel to three axes drawn in arbitrarily selected directions, and to any three scales also independently chosen. The author deals only with isometric projection, and considers two cases, first, when the projection is orthogonal, secondly, when the projectors are oblique with the plane of projection taken parallel to a face of the solid, so that figures parallel to this face appear without distortion. The best part of the book is probably the chapter giving examples, mostly of joints in woodwork, used by the author in conducting classes in manual training; but it is doubtful whether it was worth while to publish a book of such limited scope.

LETTERS TO THE EDITOR.

Eclipse Phenomena.

No opportunity for discussion was given at the Royal Society meeting last Thursday, but the following brief notes may be suggestive and possibly useful.

The particles in the corona which reflect solar light to us are presumably moving very fast away from the sun, and accordingly are illuminated by light of apparently extra-long wave-length. This light, thus lowered in refrangibility, they will emit; and inasmuch as they are probably moving at all sorts of speeds, we might expect that Fraunhofer lines would be encroached upon and blotted out from the resulting emission, especially as some particles would have a component of velocity towards us and others away from us.

If any of the particles are emitted with anything like the speed of some of those from radium, the maximum change of frequency to be expected would be great.

Particles illuminated by rays normal to our line of sight will send us a plane polarised beam, but when the illuminating rays are oblique to the line of sight, as may be the case from some of the longer streamers, then the polarisation would be only partial.

How far single electrons may be able to resist the forced vibrations of light-waves, and thus become themselves polarised sources, is a matter on which I hope to try some experiments. The illumination in which they are immersed near the sun is very intense.

The circular or ring appearance seen in the midst of the corona in some photographs, with geometric centre at a distance from the apparent centre of explosion, looked to me like a gigantic vortex ring. I see no reason why a sun-spot should not eject such rings occasionally.

OLIVER LODGE.

Geometry of Position.

IN connection with the review of Mr. Wilson's recent book, on p. vi. of your supplement last week, may I direct the friendly attention of the reviewer and your readers to an old paper of mine in the *Philosophical Magazine* for November, 1875, where some of the theorems referred to are given. I myself have found a slight modification of the rapid system of writing chemical formulæ there advocated, extremely useful, and should like to advocate its use by elementary students of organic chemistry—but that is another matter. OLIVER LODGE.

October 20.

Eclipse Predictions.

THE discrepancies referred to by Mr. J. Y. Buchanan (p. 603) as existing between the French and British predictions for the recent total eclipse of the sun are due simply to the fact that a different value of the moon's diameter is adopted in the Connaissance des Temps from that in the Nautical Almanac, the former being about $2''\cdot7$ greater than the latter. Hence the breadth of the zone of totality and the duration of totality on the central line are greater in the French than they are in the British ephemeris. But there is no occasion to impute mistake to the French calculators. They merely assume a value of the moon's diameter that is, in my opinion, too large for eclipse purposes. A. M. W. DOWNING.

Chelifers and House-flies.

IT may be that the view suggested in my letter to NATURE of August 31, that the association of the Chelifer with the house-fly is to the advantage of the former in providing it with a wider geographical distribution, is not sound. I believe it is, but at the same time admit that there is not sufficient evidence at present to prove that the association is of material advantage to the species.

The important point to determine, however, is whether

the Chelifer is or is not a parasite on the house-fly. It is fully recognised now that house-flies play an important part in the distribution of the germs of certain diseases that affect mankind. Any animal, therefore, that injures or destroys the flies may assist in checking the spread of disease. But if, as Mr. Pocock suggests, the object of the Chelifer is to feed upon the acarine parasites of its host, it serves rather as a friend than a foe to the fly, and should certainly not be called a parasite.

There is no anatomical reason for believing that the Chelifers that have been found on flying insects are specially adapted to a parasitic mode of life, nor is there any evidence that the house-flies they are attached to are infested with mites or any other skin parasites. If the Chelifers are not parasitic on the flies, and there are no mites for them to attack, how can the association of the two forms be accounted for otherwise than by the transportation hypothesis?

Since I wrote my last letter to you I have found that this matter has been most fully discussed by Mr. Kew in his article on Lincolnshire Pseudoscorpions in the *Naturalist* for July, 1901, and I would refer readers of NATURE who are interested in the subject to that paper for fuller particulars. SYDNEY J. HICKSON.

The Rudimentary Hind Limbs of the Boine Snakes.

IT is a well known fact that the pythons and boas and some allied forms among snakes possess rudiments of hind limbs, these vestiges—to quote Boulenger's "Catalogue of Snakes in the British Museum"—"usually terminating in a claw-like spur visible on each side of the vent." These structures are always mentioned in general works upon Ophidia, such as Hoffmann's account of the serpents in vol. vi. of Bronn's "Klassen und Ordnungen des Thierreichs," and Gadow's "Reptiles and Amphibians" in the "Cambridge Natural History." But in none of the three treatises to which I refer is there any further account of the "claws" or "spurs." It is merely stated that they are present. It is not mentioned in these works, nor in some others which I have consulted, that the claws in question offer valuable sexual characters by the aid of which individuals can be referred to their proper sex, at least in certain Boidæ. The fact that these characters have been so largely overlooked is perhaps due to the slight stress laid upon them by Duméril and Bibron (*Erpétologie Générale*, vol. vi., 1844), who, however, did direct attention to the occurrence of differences in these organs between the two sexes in a number of Boidæ. But they speak of the claws merely as being "d'une très petite dimension chez des femelles," and as "plus développés chez les males que chez les femelles." The first of these quotations refers to Eunectes, the second to Boa. The differences, however, in *Eunectes notaeus* are greater. In this southern anaconda, of which several specimens were lately deposited in these gardens by the Hon. Walter Rothschild, there is in the male a sharp curved claw turned downwards and ridged along its lower surface. In the female, on the other hand, the representative of this claw is not a claw at all strictly speaking—if, that is to say, we mean by a claw a nail-like structure which is curved and compressed and ends in a sharp point. In the female there is a straight, blunt, horny process distinctly unlike the sharp claw of the male. In two young examples of this anaconda, which are females, the same type of horny structure is found as in the adult female. In the allied genus Eryx there are still greater differences between the two sexes. FRANK E. BEDDARD.

Zoological Society's Gardens, October 18.

A Rare Game Bird.

MR. SAWBRIDGE (p. 605) has raised one of the most perplexing points connected with bird-migration. I cannot answer for the eastern counties of England, but here, in the south-west of Scotland, we are still further from the headquarters of the quail than he is. Fifty years ago quails bred regularly in western Galloway; as a boy I recollect that two or three brace were quite a common complement to a September bag. Indeed, when a "cheeper" or undersized partridge was shot, "Put it down as a quail!" was the usual comment. These birds gradually disappeared; the last that I myself shot was about the year 1868; but an odd one has been obtained here and there in the district ever since. One, I know, was shot last month in the neighbourhood of Newton Stewart, and was reckoned such a curiosity that it was sent to the bird-stuffer. I am sorry that I do not know whether it was a young or an old bird. Besides this, other instances, if I mistake not, have been recorded in the *Field* from different parts of the country.

As to the cause of the general disappearance of quails from this district, there have been many speculations, the commonest notion being that the supply is so heavily taxed in the Mediterranean region that few birds escape to the north. Truly, when one considers the enormous consignments of quails to London, Paris, &c., there is no reason for surprise that the migrants should dwindle in number.

I have a vague recollection of being told in boyhood that about the year 1838 there was a large influx of quails into Galloway, and that they had bred there ever since, but in numbers annually decreasing. It is conceivable that a storm-driven flock may have been carried out of their bearings, and, finding food abundant and climate endurable, if not altogether congenial, remained as colonists, but that our wet summers have proved adverse to their young being reared. The fluctuation in the stock of partridges caused by the character of different seasons is very remarkable, and evidently neither the numbers nor the constitution of our quails have enabled them to survive adverse conditions of temperature and rainfall. This makes the sporadic occurrence of individuals at long intervals all the more remarkable and perplexing.

HERBERT MAXWELL.

On a New Species of Guenon from the Cameroons.

A CHARMINGLY docile species of guenon, obtained by Cross, of Liverpool, from the Cameroons, in West Africa, and recently submitted to me for identification proves to be undescribed. I propose for it the name *Cercopithecus crossi*, in compliment to the courteous proprietor of that large and well known importing house of wild animals, and for popular use the name of *Cross's guenon*. The animal is a male, apparently nearly full grown, but not entirely adult, as the condition of its teeth indicate. It is very similar to *C. moloneyi* of Sclater, in general appearance, in having the broad rufous lower back, but differs in having a large and bushy pure white beard, white throat, and bushy whiskers of black hairs ringed with white; the band across the forehead deep black instead of fulvous; sides of head speckled black and white; underside of body sooty-black speckled with white; the tail not deep black except at tip, but speckled black and white like the upper part of the back; the black on the forearm externally does not extend to the shoulder, and not much beyond the elbow; the outer aspect of thighs is black slightly peppered with white; the inside of arms below the elbow black, higher up sooty-grey; inside of hind limbs sooty-black.

The top of the head is black, the hairs sparsely ringed with white; the face, cheeks, and ears quite nude and purplish black in colour; long superciliary hairs are present; the callosities are small and purplish sooty-grey in colour.

From *C. albigularis* (Sykes's guenon) the present species differs in wanting the yellowish wash on shoulders, fore and hind limbs, and in having a brindled and not a black tail. HENRY O. FORBES.

The Museums, Liverpool, October 12.

The Absorption Spectrum of Benzene in the Ultra-violet Region.

WE were glad to see in NATURE of October 5 a letter from Prof. Hartley in which he points out the near agreement between our measurements of the bands in the absorption spectrum of benzene and those made by Prof. Dobbie and himself. He also directs attention to the work of Friederichs, who, in the case of benzene vapour,

finds the position of these bands to be consistently nearer to the red end of the spectrum. The difference in the position of the bands in the spectrum of benzene vapour and of benzene in solution only proves, of course, the applicability of Kundt's rule. We are also pleased that Prof. Hartley has been able to see the second band on our list ($\lambda=2656$), which, coupled with the fact that Friederichs has also measured it, we feel is a most important confirmation of our observations.

As regards the eighth band ($\lambda=2330$) which has been measured in the absorption spectrum of benzene vapour by Friederichs (whose work we were, of course, unaware of when we wrote our paper), we have made a most careful search for it. We have re-examined our original plates and have taken several more photographs, but have been unable to find any trace of it. We must therefore conclude that it is absent from the spectrum of benzene in alcoholic solution.

There is one other point in Prof. Hartley's letter; he says we have overlooked some points of importance in his paper with Prof. Dobbie when we state that they only found six bands. It is quite true that in their paper Hartley and Dobbie refer in their table of measurements to another band of very short persistence which they mark as doubtful at 5 mm. thickness of N/10 solution, and very doubtful at 4 mm. thickness. In the letterpress, however, they speak of only *six* bands, and in all later publications benzene is stated to show six absorption bands. In the British Association report, and even in Prof. Hartley's paper to the Chemical Society on May 17 of this year, he speaks of six bands (*Chem. Soc. Proc.*, xxi., 167). We therefore assumed that Prof. Hartley, on further consideration, had concluded that this doubtful band was not a true benzene absorption band. As we ourselves had seen no trace of this band, we in our paper before the Chemical Society (*Trans. Chem. Soc.*, lxxxvii., 1332) stated that Hartley and Dobbie had found only six bands.

Prof. Hartley's ideas and work upon the absorption spectra of organic compounds in the ultra-violet are of the greatest importance; he was the first to show how the constitution of certain compounds could be established by this means. Prof. Hartley's method of "testing" a molecule by means of its absorption spectrum, we are sure, will prove of the greatest possible value in the hands of chemists.

Action of Radium Salts on Gelatin.

HAVING occasion to give a demonstration of the properties of radium some little time ago, I determined to attempt the preparation of some of the organisms as described by Mr. J. Butler Burke.

The method employed was to sprinkle a few specks of the radium salt upon the surface of some sterilised gelatin contained in a test-tube, and then to await development. That did not take long. Almost at once a faint cloudiness appeared to start under the speck of salt which extended downwards into the gelatin, in some cases after twenty-four hours reaching the depth of one centimetre. No heating was required to bring about this "growth," which resembled to the unaided eye an ordinary mould. The experiment was made with radium preparation of varying degrees of activity, but it was soon observed that the degree of activity in the salt had little influence on the growth, a salt of radium barium bromide containing 1/1000 of its weight of active salt being nearly as efficacious as one containing 1/100. (The more pure specimens which I possess were too precious to experiment with.)

As the specimens used were composed chiefly of barium salt, it occurred to me that it might be interesting to try the effect of the pure barium salts on the gelatin. This was done, with the surprising result that the "growths" were just as easily obtained as with the radium preparation—or even more so. I have tested all the barium salts at my disposal, and find the following produce the effect:—Barium, oxide, dioxide, chloride, bromide, iodide, nitrate, acetate, tartrate, and sulphovinate, while the phosphate, carbonate, sulphate, and borate do not act. Thus the soluble salts are active, and the insoluble ones inactive.

The method adopted for the experiments was as follows:—Some clear gelatin was poured on to a glass slip and allowed to set. A tiny speck of the salt was placed on the gelatin and covered with a thin glass. This slip was then placed on the stage of a microscope and examined with a ½-inch power. At once the "growth" was seen to shoot out from the speck, and it appeared to consist of bubbles, some large, but most of them very small. Half an hour afterwards the speck had dissolved, leaving in its place a nebulous patch many times the size of the speck. The action of barium iodide is particularly rapid, while that of the hydrate is rather slow. I have tried uranium and thorium salts, both of which affect the gelatin rapidly, but do not produce the "growths." The action of these salts upon gelatin seems to point out an interesting field of inquiry, which I propose to follow.

The Problem of "Shadow-bands."

SUBSEQUENTLY to the Algiers eclipse of 1900, it occurred to me that the "shadow-bands" visible at times of total solar eclipse might be merely another aspect of the "boiling" distortions of the sun's limb inseparable from daily observations. The last few years have therefore been employed by me in studying the characteristics of "boiling" with the view of making a direct comparison of evidences at the first opportunity. This opportunity presented itself in the recent total solar eclipse observed by me at Cás Catalá, in Mallorca, on August 30 last.

Employing "Carrington's method" of projecting the sun's image with a small telescope, the first observation made at about 10 a.m. recorded the existence of two distinct layers of cloud, the lower one travelling N.E. by S.W., and the upper one W.S.W. by E.S.E., giving confused and erratic "boiling." Further observations revealed an increased prevalence of the N.E. cloud system, but the drift from W.S.W. was still in evidence. At 11.35, however, it transpired that the W.S.W. system alone prevailed, and all trace of the drift from N.E. had abated. Continuing the observation without any relaxation throughout the phase of partial eclipse until within a few minutes of totality, I was able to ascertain that the "boiling" movements along the advancing limb of the moon were throughout absolutely in agreement in every particular with the movements of distortion affecting the still uncovered limb of the sun. Observations by projection were abandoned at 1h. 18·0m. for the purpose of securing a naked-eye view of "shadow-bands." A very successful view of these was secured. Their direction of flight determined on the spot, and afterwards corrected by Dr. Hunter, of Edinburgh, by the compass, proved to be W.S.W. by E.S.E. It is noteworthy that at Palma, where the eclipse conditions were marred throughout by the cloud bank that had threatened to overwhelm us at Cás Catalá (only four miles S.W. of Palma), the "shadow-bands" were observed to take a direction N. 30° E. by S. 45° W.

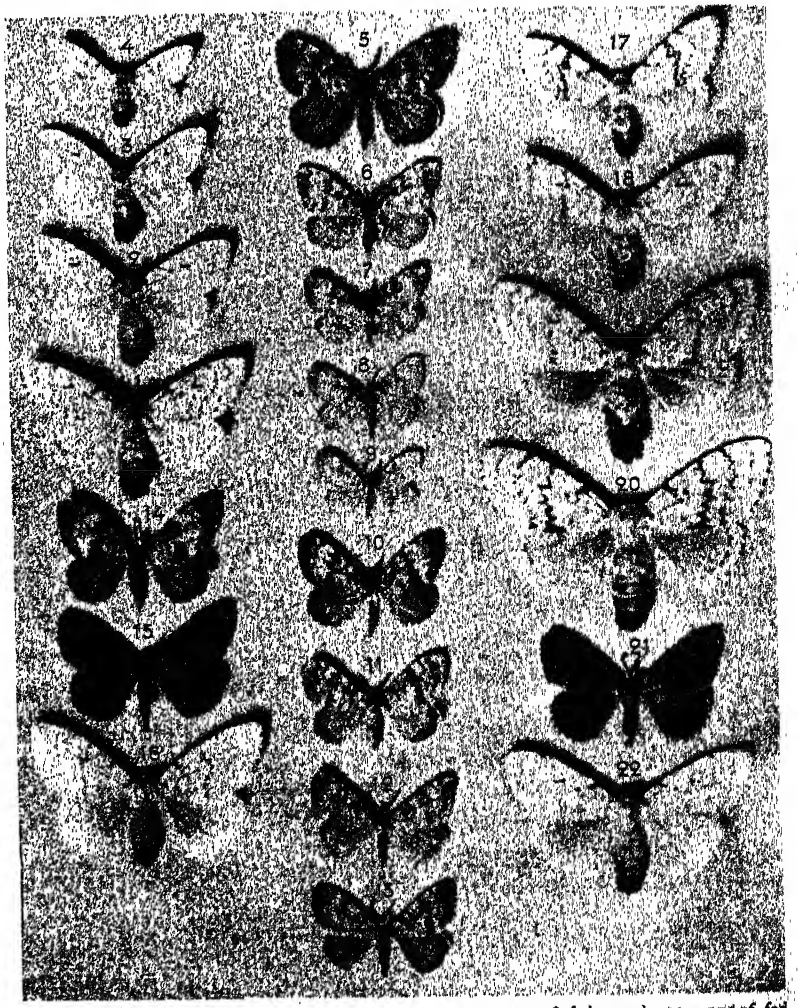
EXPERIMENTS ON VARIATIONS OF LEPIDOPTERA BY ENVIRONMENT.

An important addition to the numerous papers of recent years recording experiments as to the influence upon the forms of living beings of their environment has lately been published.[1] In this paper the inquiry is concerned only or chiefly with varieties in the pigmentation of Lepidoptera. The author enumerates as among the agents to which change in this pigmentation is to be ascribed "intensity of light, temperature, nutrition, humidity, dryness, electricity, and other meteorological phenomena." His references to the literature on these subjects are very useful. The suggestion that mechanical movement, jarring, of pupæ, might cause effects analogous to those of temperature is mentioned, but this has long since been abandoned. M. Pictet divides the variation of pigmentation into two opposite types, the one "albinism," by which red can pass into yellow and even into white, the other "melanism," by which red passes into brown and, as an extreme, into black; and this classification is kept in view all through the description of his experiments and their results. So is a theory which he puts forward, though with diffidence, that caterpillars in general were originally adapted to live only on certain special plants or trees, and afterwards, owing to finding themselves, as the result of migration or otherwise, where these were not to be had, adapted themselves to many other kinds, so as to become more or less polyphagous, still, however, in nature attaching themselves by preference to special food plants, called in this paper their normal or ancestral ones.

M. Pictet's treatment of this subject can be best illustrated by an extract:—"*Lasiocampa quercus,* known from the time of Linnæus as feeding almost exclusively on the oak, as indeed its name indicates, and the leaves of some trees and hedge shrubs, is now found frequently on ivy, poplar, sallow, birch, heath and arbutus." He does not always say what the normal food plant is, as in the case of *Phalera bucephala,* of which he states that it absolutely refuses to eat any but its normal food. In England it is found on lime, elm, willow, and many other forest trees at least as freely as on oak, and there is a record of a company found on laurel. Oak is given as the normal food of *Biston hirtarius* (found in England on a great variety of forest trees), gooseberry and spindle tree (*Euonymus europaeus*) as those of *Abraxas grossulariata.* In England this species is found in abundance also on blackthorn, &c., and it has of late years addicted itself to the *Euonymus japonicus*, an evergreen which became widely distributed in Europe during the last century. Though, as stated, it is left uncertain in some cases what M. Pictet considers the normal food plants to be, that creates little or no difficulty in appreciating most of his experiments, as the kinds of food plants which in these experiments were substituted for the foods well known to be usual were so different that they may certainly be distinguished as abnormal; for example, when walnut or laurel, or low plants such as sainfoin (*Onobrychis sativa*), dandelion, lettuce, or salad burnet (*Poterium sanguisorba*) are substituted for any of the ordinary forest trees.



FIGS. 1 and 5.—*Ocneria dispar*, typical form ♀ and ♂; 2–4, 6–13, 17, 18, fed on walnut; 14 and 16, fed on mespilus; 15, fed on dandelion plants; 20 and 21, fed on onobrychis; 22, fed on poterium plants.

Among the principal conclusions arrived at by M. Pictet are the following:—(1) Change of ancestral food plant is often a factor of variability. (2) In general, a food difficult to absorb and digest prevents the larva from developing within its usual period, and this longer larval period is associated with the shortening of the pupal period, and consequently with insufficient pigmentation. (3) Normal food plant in insufficient quantity has the same effects. (4) A food easy to take in (ingérer) and rich in nutritious elements accelerates the larval development, and thus reacts on the duration of the pupal period, which, being thus lengthened, a more intense pigmentation

[1] "Influence de l'Alimentation et de l'Humidité sur la Variation des Papillons." By Arnold Pictet. (*Mémoires de la Société de Physique et d'Histoire naturelle de Genève*, vol. xxxv., fascicule 1, June, 1905, pp. 46–127.)

ensues. . . . (8) The variations produced by food increase in intensity with each generation, and even arrive at such a point as to persist to a degree, by heredity, in the next generation brought up on normal food; when, in successive generations, the food plant is different, each kind of food plant impresses its characteristic effects on the imago. (9) After some generations on the abnormal food the insect becomes accustomed to it, and this brings about a return to the primitive type—sometimes, indeed, passes beyond it in the opposite direction.

The experiments which led to these conclusions extended over five years, from 1900 to 1904, and were tried on 21 different species and about 4695 individuals. The paper is illustrated by five plates containing eighty-one photographic figures, which are excellent, but uncoloured, so that they have not the advantage of showing the distinctive colour effects which enter into the verbal description of the results obtained. The course of experiment can only be briefly indicated here, having due regard to the exigencies of space, but I may select for reference some of M. Pictet's chief experiments on what was their principal subject, *Ocneria dispar*; on this species there were twenty-nine experiments upon 1568 individuals. In many of those tried on this and other species the differences from the normal, so far as they are shown by the plates, are not very distinguishable from those deficiencies in intensity and definiteness of marking and the dwarfing of size that one is accustomed to find when larvæ are bred on food that is insufficient or unsuitable, to put it in a popular form, are "half starved." It is right, however, to say that M. Pictet considers, as afterwards mentioned, that in those examples which he has selected for illustration as exhibiting the effects of abnormal food plants, walnut, onobrychis, &c., they are distinguishable from each other to such an extent that where larvæ have been fed for three successive generations on walnut, onobrychis, and oak respectively, the special influences of all three food plants can be seen.

In six experiments with *O. dispar*, walnut was given for one or more generations; in all these cases the wing expansion was considerably smaller than normal, in some cases not more than three-quarters or two-thirds of it. Where *O. sativa*, dandelion or *P. sanguisorba* was given the imagines were considerably larger than normal, but when in one or more of the succeeding generations walnut was substituted the size was immediately reduced, much as in the other six experiments. *Mespilus germanicus*, horse chestnut, white poplar, and sallow had effects very similar to those of walnut. In experiment (4), where oak in the second generation succeeded walnut in the first, there was a slight return towards the type, but when in the third generation walnut was again given, the failure in intensity of markings reached its minimum, there being scarcely a trace of colour; when, however, in the fourth generation oak was again given, there was a nearer return towards the type than the second generation showed. In other cases the "albinistic" influence of the walnut persisted in a very marked degree after two later generations fed on oak or on *O. sativa*. In such cases, also, where other food plants of the three different classes ("albinising," "normal," and "melanising") had been given in succession, M. Pictet considers that the special pigmentation effects of each of the three kinds of food plant are shown by the imagines of the latest generation. These are for walnut, ♂, pale yellow colour, two central lines partly obliterated, other markings less intense; ♀, wings slightly transparent, few markings on upper wings, more on lower; second generation, ♂, wings whitish, marginal band on all partly obliterated, transverse lines little visible; ♀, wings transparent, the V mark and the marginal dots alone appearing; for *O. sativa*, ♂, wings brown, zigzag, lines little noticeable, marginal band very dark, abdominal hairs greyish; ♀, on upper wings white zigzag lines strongly marked; for *dandelion*, ♂, very similar, only the lower wings of uniform dark colour.

M. Pictet arrives at the general conclusion that the "albinising" variations are caused by the larvæ having been fed on leaves presenting obstacles to nutrition, such as hard cuticle or felted underside, as in white poplar, and that, on the other hand, the "melanising" variations are caused by food presenting no such obstacles; thus the young leaves of laurel are not "melanising" as the old leaves are. So far as I am aware, M. Pictet's conclusion that a difference of food plant in one generation can cause a difference of facies in the imago, and one that persists for several generations, is not in accordance with views hitherto prevailing; its bearing on the question whether a quality thus acquired can originate a new permanent variety or species is, however, at least materially affected by M. Pictet's other position, that where several generations have been brought up on the abnormal food so as to become accustomed to it, they revert towards the original form, so that there would appear to be only a temporary disturbance in the colouring of the species.

All M. Pictet's figures of *O. dispar* are reproduced as illustrative of this notice; those numbered 13 (walnut, oak, onobrychis), 14, and 16 (onobrychis, mespilus) are relied on by him as showing indications of each of the different food plants supplied to them and their ancestors, that numbered 10 (walnut, oak, walnut, walnut) as showing reversion towards the original normal form when the larvæ have for several generations been confined to abnormal food.

With respect to M. Pictet's position that an inverse rate of development in the pupa is caused by lengthening or shortening the duration of the larval "diapause" or period of repose, his experiments favour that view; but it will hardly be accepted as of general application without further experiments.

There is a section on the influence of food on the colour of the larvæ in which M. Pictet states that such an influence is exerted, with observations tending to show that in some cases there is a relation between the colour thus induced in the larva and the colouring of the imago. There are also experiments from which he draws the conclusion that the kind of food influences the secondary sexual characters of the larvæ which are so marked in *O. antiqua*, &c.; this does not, of course, mean that it changes the sex as has been asserted; on that he makes the just observation that it is not sufficient to count the respective numbers of males and females among the perfect insects obtained, but account ought also to be taken of those that die, usually in large numbers, and the male sex may be much more capable than the female of supporting the "tribulations of life," among which, one may add, must certainly be included scientific experiments on their food.

The second part of M. Pictet's paper is devoted to the influence of humidity. Excessive moisture applied to young larvæ is largely fatal, but seems to have no effect on the perfect insects which survive, beyond slightly reducing their size. Older larvæ, *i.e.* (usually) for the period of eight or ten days before pupation, resist it perfectly, but give "aberrations," some of which are figured, such as are met with here and there in nature.

The paper is a valuable contribution of facts to the solution of questions of much interest, and M. Pictet's conclusions as to the causes of the results he describes are well worthy of the consideration that they will doubtless receive. It is to be presumed that he took all proper means to isolate the influences he applied from other influences, but his arguments would perhaps have gained in force if he had stated in detail what steps he had taken to ensure this isolation. For example, in his experiments on the colouring assumed by larvæ, though he is acquainted with the experiments of Prof. Poulton and others, showing the undoubted effect of a few coloured surroundings on the colouring of the larvæ of many species, it does not appear what precautions were taken to exclude the operation of such surroundings; nor in the experiments on the duration of the pupal stage when the larval "diapause" was shortened, or in the humidity experiments, does it appear that the temperatures during all the time of the pupal stage were noted; it is known that a very moderate difference in temperature will make a difference of many days in the duration of this period. One may venture to suggest, also, that in the continuation which it is hoped M. Pictet will make of his valuable experiments he will give as far as possible the whole number of the insects in the broods at their commencements and the whole number of perfect insects reared —in the great majority of cases only percentages are given; also that he will state whether the whole or nearly the whole of those reared were similar in appearance to those figured, and whether there was any considerable proportion substantially different.

There appears to be one error to which, as it has not the character of a mere slip, and therefore has a bearing on the arguments used, it is necessary to direct attention. The larvæ of the first generation of the year of *V. urticae* are at p. 94 mentioned as coming from butterflies which "have probably passed the winter in the chrysalis stage," and at p. 81 "certain Vanessas" are spoken of as being able to pass the winter in the egg, chrysalis, or winter stage. Surely *V. urticae* hibernates only as an imago, wherever there is a real winter, as is the habit of the Vanessas generally. Again, fifteen to twenty days is stated as the usual period of the larval life of *Argynnis paphia*; in England this hibernates as a very young larva, and feeds up, very quickly it is true, during April, May, and June, appearing as an imago in July or early August, and this is its usual habit on the continent of Europe.

F. MERRIFIELD.

CHEMISTRY IN THE SERVICE OF THE STATE.[1]

IN the year 1840, the Legislature made an interesting fiscal experiment. It repealed all previous enactments against the adulteration of tobacco, and permitted any ingredients, "except the leaves of trees, herbs, and plants," to be added to that article in the course of its preparation. The result was that tobacco speedily became grossly adulterated; in two years the consumption had decreased by more than a million pounds; and, since tobacco is a heavily taxed commodity, the Exchequer suffered severely. So serious a loss had to be promptly stopped; hence in 1842 the prohibition of adulteration was re-enacted. To help in making the prohibition effective, the Commissioners of Inland Revenue fitted up a small laboratory, the staff of which, consisting for some time of one person only, was occupied solely in detecting fraudulent additions to tobacco.

Such was the modest origin of the chief branch of the institution which now undertakes nearly all the analytical and consultative chemical work required by the various Government departments. Another branch, the Customs Laboratory, may be said to owe its inception chiefly to the Sale of Food and Drugs Act, 1875, which laid upon the Board of Customs the duty of supervising the quality of imported tea. The two branches were affiliated in 1894 under one head.

How considerable the business of the laboratory has now become may be gathered from the recently issued report of the principal chemist, describing the work of the department during the last financial year. From this it appears that the number of samples analysed in that period was no less than 138,508. Of these, 49,751 were examined in the Customs branch, and the remainder, 88,757, in the main laboratory at Clement's Inn Passage.

What, however, more particularly strikes one is the wide range of interests, both of the State and of the individual, which are touched at one point or another by the chemical activities of the department. We extract from the report a few notes which may serve to illustrate this, and to indicate the nature of the questions dealt with.

Dealing first with the Customs, the ultimate aim of the various analyses is, of course, to facilitate the just assessments of Customs dues. This, however, involves the testing of many articles which are not themselves dutiable. For instance, genuine cider is free of duty. A temptation is thus offered to an unscrupulous wine importer, since by labelling his wine as "cider" he may, if undetected, get it passed into the country without payment. As a matter of fact, out of 154 samples examined during the past year, 10 represented importations of so-called "cider" which was found to be chargeable as wine, and another had to pay duty as a spirit preparation. Again, crude methyl alcohol is admitted free, but if purified so as to be potable must pay the spirit duty. In 31 cases out of 256 the substance was, in fact, so pure that the full alcohol rate was levied.

As compared with the previous year, there has been a notable decrease in the number of certain beer, wine, and liqueur samples; this is attributed to diminished consumption of alcoholic beverages. On the other hand, samples of tea show a considerable increase—from 2345 to 3260—in spite of an augmented tea-duty. For various reasons, 316 of these specimens of tea were objected to, and 7 were condemned as unfit for human food.

Among other items of interest, we note that facilities are given by the Customs authorities for the utilising of waste tobacco in the preparation of sheep dips and similar articles. It appears that nicotine is supplanting arsenic as the active principle in such products.

The very high duty on saccharin—20s. per pound—involves, the principal chemist remarks, a careful outlook for this substance in the most unlikely places. 617 samples of articles which might have been vehicles for its fraudulent introduction were tested, and 55 of the number were charged the duty as being either saccharin or substances of like nature and use.

In the laboratory at Clement's Inn Passage, the business is classed as (1) Revenue work; (2) work for other Government departments; and (3) the analysis of samples referred by magistrates to the Government chemists in disputed cases under the Sale of Food and Drugs Acts. The examinations of excisable articles are devised to secure the revenue accruing from beer,

[1] "Report of the Principal Chemist upon the Work of the Government Laboratory for the Year ending March 31, 1905." Official Publication, Cd. 2591. Price 3*d*.

spirits, and tobacco. For instance, beer-duty is charged according to the specific gravity of the brewer's wort before fermentation, and this gravity is "declared" by the brewer himself. To test the accuracy of such declarations, 6370 samples of wort in various stages of fermentation were analysed, with the result that the amount of duty was increased in more than 10 per cent. of the cases. Again, on beer which is exported, "drawback" corresponding to the original duty can be claimed: to check the claims, samples of the beer are analysed; and during the year 2789 barrels were found to be not entitled to the drawback claimed. 813 samples of beer out of 6589 taken from publicans were shown by analysis to have been illegally diluted with water. Of so-called "temperance" drinks, about one-third of the whole number examined, 1011, contained alcohol in excess of the legal limit, the highest quantity being about as much as in ordinary light beer. Forty-four specimens of beer and brewing materials were found to contain arsenic in objectionable amount.

As regards spirits, it is noted that the exportation of medicinal tinctures, flavouring essences, and perfumes is increasing. So, too, is the use of denatured alcohol for industrial purposes, and of pure duty-free spirit issued to medical and other science schools.

Tobacco is examined chiefly to prevent an excessive admixture of water or oil; penalties were imposed in 87 cases of this kind during the past year, and also in other instances where glycerin and liquorice were unlawfully present.

Legal proceedings are necessarily a feature of the chemical control over dutiable articles. Penalties aggregating 5072*l.* were imposed during the year in respect of offences proof of which depended upon the analytical evidence.

Much work, of very varied scope, is carried out for the Admiralty, the Boards of Trade and Agriculture, India Office, Post Office, War Office, and other State departments. Imported dairy produce, for instance, is analysed for the Board of Agriculture in order to check the importation of adulterated foodstuffs; 2468 such articles were examined in the year, of which 2110 were butter and 305 milk and cream. Boron preservatives and artificial colouring-matter are found to be common additions to the butter. The use of the preservative is increasing; but, as the principal chemist points out, there is a difficulty in restricting the admixture so long as a legal limit has not been fixed. In two other respects it would seem that the law might well be amended. Butter, about the purity of which there were grave doubts, and cheese containing merely nominal amounts of fat, had, "in the absence of legal limits," to be admitted into the country without objection; this seems hardly fair, either to the home farmer or to the consumer.

In connection with the testing of filters, a useful note of warning is given to the makers of these articles. The actual filtering material may be quite satisfactory, but as regards giving a sterile filtrate the whole apparatus is sometimes rendered useless by leakage of unfiltered water through faulty fittings.

For the Home Office an interesting series of lead-glaze samples was examined during the year. It may be remembered that cases of lead poisoning in the pottery industry had a few years ago become so numerous as almost to constitute a public scandal. Profs. Thorpe and Oliver, who were commissioned by the Home Secretary to investigate the matter, recommended, among other remedial measures, the substitution of lead silicates for the white lead then in general use as a glazing substance, on the ground that the silicate, properly compounded, would be almost insoluble in the acids of the gastric juice, and therefore far less poisonous than the easily soluble white lead. Based on this recommendation, a regulation was framed by the Home Office; it was, however, thought by the potters to be too stringent, and eventually the point was submitted to arbitration, Lord James of Hereford being umpire. His award was in the nature of a compromise giving the manufacturers greater freedom than under the original proposal. The conditions are set forth in the report, together with the results of the analyses of samples of glaze showing how nearly the manufacturers, in the first year's working of the new rules, have been able to keep their glazes within the specified limits. On the whole, the results are fairly satisfactory. Thus thirty samples were represented as "leadless," and all but four did, in fact, conform to the regulation.

The India Office requires the analysis of a great variety of articles, which are examined in order to ensure that goods supplied by contractors are actually what they purport to be. Metals and alloys, cements, chemicals, disinfectants, drugs, food preparations, oils, paints, and surgical dressings were among the supplies sent for analysis during the year; but how far they proved to be satisfactory is not stated.

In cases which arise under the Sale of Food and Drugs Acts there may be a conflict of testimony, and the magistrate may wish to have before him independent evidence upon the chemical aspects of the question. In such matters the Government Laboratory acts as *amicus curiae,* and examines a sample of the article in dispute which has been specially reserved for that purpose. Further, whether the magistrate wants it or not, either of the litigants can claim to have this reserved sample forwarded for analysis. This is an excellent provision, securing as it does a careful examination of the disputed points by chemists unconnected with either prosecution or defence, and detached from any local influences which might, however wrongly, have been alleged or suspected by an accused person to have been used against him. During the past year this provision has been taken advantage of in 109 instances. The net result of the references was to support the allegation brought against the article in the great majority of cases, viz. in 95 out of 105.

The report bristles with matters of interest similar to the foregoing. It is the record of a useful year's work.

ON THE ORIGIN OF EOLITHS.

The more detailed paper by M. Marcellin Boule on the subject of the origin of eoliths (see Nature, August 31, p. 438) has now appeared in *l'Anthropologie* (Tome xvi., p. 257), and was briefly noticed in Nature of September 28 (p. 538). The paper is too long for us, with the existing pressure upon our space, to give a full translation of it, but the following are the principal new features in the extended essay. The velocity of the circumference of the wheels in the *délayeurs,* or vats, is stated to be about 13 feet per second, the same as the speed of the Rhone in times of flood. It will therefore be seen that these mixing vats are of an entirely different character from ordinary pug-mills, and that the motion of the water in them may be properly described as torrential. The author attaches no importance to the fact that some of the blows to the flints are given by the iron teeth of the suspended harrows, and states that most of the flints are reduced to the condition of rolled pebbles, identical with those to be found in all flint gravels, but that there are numerous examples of *rétouches,* or secondary working. In illustration of this he gives photographic figures of eleven different specimens by which he contends that

the analogy of these flints from the cement manufactory near Mantes with the so-called eoliths from Tertiary beds is substantiated, and he regards it as undeniable that these Mantes eoliths have been produced, and are being continually produced, apart from the intention of any human being.

In conclusion, he directs attention to the importance of migration both in history and in the development of all fossil groups. Nothing, he says, proves that the evolution of the human species or genus took place in one particular spot. It is very possible that man appeared suddenly in this part of the world at the beginning of the Quaternary period, at the same time as the mammalian fauna of which he forms part, and which is very different from the last fauna of Pliocene times. As a palæontologist, he believes firmly in the existence of Tertiary man, traces of whom, he doubts not, will eventually be found in some part of the world; but for these to be indisputable, they must possess a very different value from that of the eoliths.

In addition to M. Boule's memoir, an important article has appeared in the *Archiv für Anthropologie* (Neue Folge, vol. iv., p. 75), "Zur Eolithenfrage." It is from the pen of Dr. Hugo Obermaier, of Paris, who has also visited the cement works near Mantes, and entertains views upon the subject almost identical with those of M. Boule. He begins with a historical sketch of the discoveries of eoliths in beds from the Oligocene downwards to the Quaternary, and then proceeds to describe and discuss the modern products of the *délayeurs*, of one of which he gives a section. The paper is illustrated by eight plates, six of which are photographic. The first gives eight specimens of reputed eoliths from Miocene beds at Duan, near Brou (Eure et Loire). The other five are devoted to examples from Mantes, not a few of which present the "hollow-scraper" notches so often seen on eoliths. The remaining two plates contain reproductions of wood-cut figures of eoliths from various localities, so as to afford means of comparison between the old and the new.

He directs attention to an admission of M. Rutot that the eolithic industry is confined to localities where two conditions exist, the one that there was an abundance of the raw material flint, and the other that there was a stream of water in the neighbourhood, conditions which, in a modified form, exist at Mantes.

Want of space precludes a longer notice of this interesting article. We may, however, quote Dr. Obermaier's words in a letter to the editor of the *Archiv für Anthropologie* (Neue Folge Corr. Blatt., July, 1905, p. 50):—"We have now an experimental proof that eoliths can be formed in a purely mechanical manner."

NOTES.

As already announced, the inaugural meeting of the British Science Guild will be held on Monday next, October 30, at the Mansion House, at 4.15 p.m. The Lord Mayor will preside, and will be supported, among others, by the Lord Bishop of Ripon, Lord Strathcona and Mount Royal, the Right Hon. R. B. Haldane, K.C., M.P., Admiral Sir Cyprian Bridge, G.C.B., General Sir Frederick Maurice, K.C.B., Sir John Wolfe-Barry, K.C.B., F.R.S., Sir William Ramsay, K.C.B., F.R.S., Mr. C. W. Macara, and Sir Norman Lockyer, K.C.B., F.R.S.

A MEETING of the general committee of the British Association will be held in the rooms of the Linnean Society, Burlington House, on Tuesday next, October 31, at 3 p.m., for the purpose of appointing officers for the meeting of the association to be held at York next year, and of deciding upon the place of meeting in 1907.

THE Paris correspondent of the *Times* states that M. Gérault-Richard proposes to ask the French Parliament to vote a credit of 100,000 francs (4000*l.*) for the investigation of the best means of combating tuberculosis. The Minister of Education, M. Bienvenu-Martin, has promised the support of the Government.

THE death is announced of Prof. DeWitt Bristol Brace, head of the department of physics in the University of Nebraska, and one of the leading physicists of the United States. He was in his forty-seventh year, and had just entered upon his nineteenth year of teaching in the University of Nebraska.

AN international exhibition in connection with ceramic industries, and with the manufacture of glass and crystal, will be held in 1906 from June to October at the Champs-Elysées and the Cours-la-Reine. Full information can be obtained from the director-general of the exhibition, 19 rue Saint-Roch, Paris.

WE learn from the *Pharmaceutical Journal* that the Heriot trust governors have decided to establish a laboratory at the Heriot Watt College, Edinburgh, for the study of bacteriology in its relation to various industries. The laboratory has been fitted with the best appliances, and the services of Dr. Westergaard have been retained to supervise it. The laboratory was formally opened by a lecture by Prof. Hansen on October 18.

A STRONG earthquake shock was felt in Constantinople on October 22 at 5.55 a.m. The disturbances, which lasted several seconds, appeared to travel from the north-east towards the south-west, and were accompanied by a rumbling noise. Earthquake shocks were felt at 2 p.m. on the same day at Batum, and between 2 p.m. and 5 p.m. at Kutais. An undulating tremor lasting forty seconds was also experienced at Sukhum-Kaleh.

A CONFERENCE of delegates from the corresponding societies affiliated to the British Association will be held in the rooms of the Linnean Society on Monday and Tuesday, October 30 and 31, under the presidency of Dr. A. Smith Woodward, F.R.S. Among the subjects to be discussed are "The Preservation of Native Plants," to be introduced by Prof. G. S. Boulger, and "The Law of Treasure Trove," which will be introduced by Dr. W. Martin. The delegates will visit the museum of the Royal College of Surgeons, and will dine on Monday evening as guests of the Royal Societies Club.

A REUTER message states that the Berlin Meteorological Observatory, which the Emperor recently opened in the presence of the Prince of Monaco, is fitted with all the latest appliances for meteorological research. The Emperor attaches great importance to the use of balloons in meteorology, so that an extensive balloon hall has been included in the building plan of the new observatory at Lindenberg, near Berlin. On the highest point of the plateau on which the observatory stands is a shed which can be turned to any point of the compass, and contains a cable drum driven by a small electric motor for hauling in kites, which are to be extensively used for meteorological purposes. Electric search-lights have also been installed for night observation. Another interesting feature of the new institute is the kite factory, where large kites, fitted with self-registering instruments, are made. The institute has its own establishment

where balloons can be filled, and it is the present intention of the directors to make observations with balloons every first Thursday in the month.

DR. BÁTHORI ENDRE, writing from Királyfalva, Hungary, informs us that the Bólyai international prize will be presented next December, for the first time, by the Hungarian Academy of Sciences. The prize is ten thousand crowns, and will be awarded every five years, in memory of John Bólyai, the celebrated Hungarian mathematician, to the writer of the best mathematical work in the same period of years. The committee concerned with the award of the prize met on October 11 in Budapest. The members of the committee are:—Prof. G. Darboux, Paris; Prof. F. Klein, Göttingen; Prof. G. König, Budapest; and Prof. G. Rados, Budapest. The names of two mathematicians were considered, viz. Prof. H. Poincaré and Prof. D. Hilbert. The committee awarded the prize to Poincaré, and at the same time expressed its acknowledgment and admiration of Prof. Hilbert's works. Profs. Darboux and Klein gave lectures in Budapest on the teaching of mathematics.

THE inaugural address of the Manchester Literary and Philosophical Society was delivered, on October 17, by Sir William H. Bailey, the president of the society. The address took the form of an interesting historical account of the society since its foundation in 1781, and included appreciative references to the work of many distinguished members whose names are to be found in early volumes of memoirs. The founders were the chief scientific men of Manchester. Among the honorary members were Erasmus Darwin, Dr. Franklin, Lavoisier, Dr. Priestley, William Roscoe, of Liverpool, the poet and grandfather of Sir Henry Roscoe, Dorning Ramsbottom, Josiah Wedgwood, and others. The chief tools of the workshops of the world, not only those where steam engines, locomotives, and steamships are built, but also of the textile factories of the world, were invented in Manchester or within thirty miles of it. The records of the society contain the names of many of these inventors who were members, for the men of Lancashire were the first to use steam power for spinning and weaving, and for punching, cutting, and shaping metal. Prominent among the inventors was that genius Richard Roberts, who was always in the front rank in advocating technical education. His chief inventions were the slide lathe, planing machine, and self-acting mule for spinning cotton. Then there was Nasmyth, the inventor of the steam-hammer, Sir William Fairbairn and Sir Joseph Whitworth. Finally, Sir William Bailey referred to the great work of the illustrious members Dr. Dalton and Dr. Joule, whose effigies in marble are in the entrance to the Manchester Town Hall.

PLANS have been formulated by Mr. Einar Mikkelsen, a young Dane, for an expedition to the Arctic regions, the objective being that part of the Polar Ocean which lies immediately to the west of the Parry Archipelago, north of Canada. Interviewed by a representative of the *Morning Post*, Mr. Mikkelsen gave an outline of his programme. He will be joined by Mr. Leffingwell, a young American geologist, and Mr. Ditlevsen, a naturalist, who, like Mr. Mikkelsen, accompanied Lieut. Amdrup to the east Greenland coast in 1900. It is proposed to start from Canada in the spring of 1906. Early in May the party hopes to reach the upper waters of the Athabasca River, by way of Edmonton, and to follow that stream, and the Slave and Mackenzie Rivers, down to the northern coast of the Dominion. It will be some time in July before the mouth of the Mackenzie River is reached. At the end of August a whaler, which will have been brought north especially for the use of the expedition, will be joined by the party. Geological and zoological investigations and study of the native Eskimo will occupy the time of waiting. At Cape Kellet it is hoped that winter quarters will be established. The winter is to be occupied with scientific investigations. The plan is that about the end of February the party, three white men, two Eskimo, and the dogs, shall start out from Prince Albert Cape in a N.N.W. direction, that is, more or less parallel to the mainland. Ten days, it is calculated, should see an end of the bad ice, and then Mr. Ditlevsen is to return, leaving Messrs. Mikkelsen and Leffingwell to continue the journey alone. They hope to keep on in the same direction as far as latitude 76° N., in about 147° west longitude, before turning south to reach the coast.

THE Tottenham Urban District Council has issued a public appeal for subscriptions for the purpose of furnishing a museum and for the donation of objects of interest. An opportunity occurred during the present year for securing a collection of minerals and other geological specimens for a nominal sum, and at the same time an offer was received from Mr. H. E. H. Smedley to lend his museum collection to Tottenham and to give his services as honorary curator. The council has accepted the offers. The cost of furnishing the museum is estimated at 250*l*. Any contributions in money, or suitable objects for exhibition, may be sent to the librarian at the Central Public Library, High Road, Tottenham.

THE increased sale of synthetic indigo promises, a writer in the *Journal of the Society of Arts* states, to destroy the old and important Anglo-Indian industry of indigo planting. Since 1895–6 the value of the exports has fallen from 3,569,700*l*. to 556,400*l*., and this is largely due to synthetic indigo. Of the indigo imports of Japan last year fully three-fourths was the artificial product, vegetable indigo being increasingly unsalable. In the United States the synthetic dye came on the market in 1898, and was held at 44 cents per pound, about the value of vegetable indigo on the indigotin basis. Now the price is down to 18 cents, and at this figure it is claimed to be much cheaper than the lowest obtainable values in any vegetable indigo. The artificial dye has already secured nearly 85 per cent. of the world's consumption, and the price of indigo has dropped about one-half. To-day Germany imports only small quantities of natural indigo, while her exports of synthetic indigo have increased enormously, and represented last year a value of 25,000,000 marks.

THE study of the zoology of the Philippines is being energetically carried on by the Americans, one of the latest contributions being the description of new Hymenoptera, by Mr. W. H. Ashmead, published in the *Proceedings of the U.S. Nat. Museum* (No. 1416).

THE Agricultural Society of Sapporo, Japan, is devoting its energies to the study of the insects of the country and the mischief they inflict on agriculture, forestry, &c. In the first and second parts of the second volume (the first volume being at present apparently unpublished) of the society's journal, of which we have been favoured with copies, all the papers except one are, for instance, devoted to insects and their life-history. The groups discussed include the Cercopidæ, or lantern-flies, the freshwater Hemiptera, and the bark-boring beetles of the family Scolytidæ. In the article referred to above, Mr. S. Hashimoto takes into consideration the composition of certain abnormal samples of milk.

THE papers in the *Zeitschrift für wissenschaftliche Zoologie* (vol. lxxx., part i.) include one by Mr. V. Widakowich on the structure and function of the so-called nidamental organs (that is to say, the glands which secrete the white and shell of the eggs) of the shark *Scyllium canicula*. In a second Mr. A. Reichensperger describes the anatomy of the living West Indian crinoid *Pentacrinus decorus*. A third, by Mr. O. C. Glaser, is devoted to certain features in the physiology of the American gastropod *Fasciolaria tulipa*, while in a fourth Messrs. Marshall and Dernehl commence a dissertation on the embryology and anatomy of the hymenopterous insect *Polistes pallipes*.

To the first part of the eightieth volume of the *Zeitschrift für wissenschaftliche Zoologie* Dr. O. Grosser communicates an interesting paper on the evidence that certain dermal structures or markings among vertebrates have a segmental origin. Among the features referred to are the transverse arrangement of the scaling on the under surface and sides of the body in lizards, and the transverse colour-bands on the bodies of the banded mongoose (*Crossarchus fasciatus*), the tiger, and the zebras. In regard to the scaling of reptiles, the author admits that the transverse arrangement is very probably a secondary feature due to adaptation to the movements of the body, while he adds that the evidence for the segmental origin of the transverse stripes in mammals is purely of a negative nature, and requires something much more definite in its favour before it can be accepted. It may be added that if this segmental origin of colour stripes be accepted, it at once cuts away the ground from those who regard it as a special protective adaptation.

WE have received the first part of a work, to be completed in six parts, price sixpence each, entitled "I go a-walking through the Country Lanes." No author's name appears on the title-page, but the text is stated to be compiled from the Rev. C. Johns's "British Birds and their Haunts." Each part is to contain reproductions from photographs taken by Mr. Reid, of Wishaw, the incomparable excellence of which needs no commendation on our part. The aim of the book is "to outline a walk in the country, and to describe and picture the habits of the birds and the animals that are to be seen." The photographs in some instances might have been made to convey more information. On p. 13 we have, for instance, a charming picture of a flock of sheep coming out of a field, to which the legend "changing pastures" is subscribed. It would surely have been just as easy to mention that these sheep, as shown by their white faces and long wool, are Leicesters, or some nearly kindred breed.

THE Selborne Society has issued an illustrated circular in which attention is directed to the objects coming within the purview of that body, and the privileges enjoyed by members. "Birds in the Field and Garden" is the title of an article in the October issue of *Nature Notes*, the official organ of the society, in which the nameless author, while admitting that a certain amount of damage is inflicted on fruit and other produce, maintains that, on the whole, the visits of birds are advantageous alike to the gardener, the fruit-grower, and the farmer. In connection with this subject, it may be mentioned that we are acquainted with certain gardens where, owing to the damage done to the buds by bullfinches and other members of the finch tribe, the whole of the gooseberry and currant bushes have been enclosed in wire netting with a mesh small enough to prevent the entrance of birds. The experiment has been carried on for two seasons with the most satisfactory results, and there has been no necessity to take any special steps to free the bushes from insects. Here, then, is a problem for those who urge that birds are essential to the gardener.

IN *Biologisches Centralblatt* for October 1 Mr. W. M. Wheeler, of the American Museum of Natural History, and Father E. Wasmann discuss the discovery of "temporary social parasitism" among ants, and the inductions to be drawn therefrom as to the origin of "slavery" among certain members of the group. Mr. Wheeler claims to have been the first to describe this temporary parasitism in a *Bulletin of the U.S. National Museum* issued in October, 1904; but the corollaries from this discovery and inferences in regard to the general origin of slavery among ants were not published by him until the middle of February of this year. In conclusion, the writer urges that none of the observations published by Father Wasmann during all the years he has been engaged in the study of ants "are sufficient to accredit him with the independent discovery of temporary social parasitism as a general and regular phenomenon among certain Formicidæ." In a reply to this article, Father Wasmann very candidly admits that Mr. Wheeler is fully entitled to the credit of this discovery, although he apparently does not accept certain other claims made by the American naturalist

"CAN fish hear?" is a question discussed by Dr. O. Körner in a special issue of the *Beiträge zur Ohrenheilkunde*, published to commemorate the seventieth birthday of Prof. A. Lucae. The question is provisionally answered in the negative, and for the following reasons. It seems that many fishes are able to perceive rapid, consecutive vibrations communicated to water, but that such vibrations are taken cognisance of by means of the so-called auditory organs is highly improbable. This is supported by the fact that single loud explosions in water were totally disregarded by fishes belonging to no less than five and twenty distinct species of fishes. Moreover, the circumstance that the presence of the senses of sight and touch is easily demonstrable in fishes renders it probable that the same would be the case with hearing if it existed. Finally, the fact that fishes, and apparently also such isolated forms in other groups as are deaf, alone among vertebrates possess no organs comparable to the Cortischian nerve-terminations renders it probable that these organs are alone capable of transmitting auditory vibrations, the hypothesis that such vibrations may be received by the vestibular apparatus not being at present substantiated.

WE have received part ii. of an illustrated catalogue of the ethnographical collection of the Sarawak Museum (Journal No. 43, April, Straits Branch, Royal Asiatic Society), by Mr. R. Shelford. This section deals only with the objects worn for decorative purposes by the natives of Borneo. The question of the relationship between magic and personal ornamentation has not been lost sight of, but many inquiries have elicited little information of importance. Kalabit youths when visiting new districts wear a necklace of decorative seeds as a charm against evil spirits, and Land-Dyak men wear a necklet of beads and canines of leopard and bear for a similar purpose; the beads are frequently regarded as charms against specific diseases. The leglets of finely plaited fibre so commonly worn were at one time employed as currency; the Kayans say they feel quite naked if they do not wear these leglets. The catalogue is very well done, and is illustrated by adequate plates. If the whole museum is treated in this way the catalogue will prove to be a very valuable record of the ethnography of Sarawak.

THE *Bulletin du Jardin impérial botanique de St. Petersbourg*, vol. v., part iii., contains a description of new lichens from Central Russia and Siberia, by Mr. A. Elenkin, and an account of the vegetation on the chalk cliffs in the basin of the river Choper, by Mr. W. Dubjansky.

IN his report for 1904–5, the curator of the botanic station in Dominica states that spineless lime plants are in great demand, but that he is unable to furnish an adequate supply, as the fruits contain very few seeds; also, owing to the labour involved, the supply of budded orange stock is limited. Other plants in request are cacao, rubber—both Castilloa and Funtumia—and ordinary limes. Judging from the manurial experiments with cacao, extending over three years, the application of phosphate and potash with dried blood may be expected to give substantial increases in yield, while mulching with grass has produced even better results.

THE Department of Agriculture for British East Africa has issued a leaflet on the cultivation and commercial products of the cocoanut. The industry is one that requires some capital, as the plants only come into bearing in the sixth year, and meantime the cultivator is dependent upon the maize, ground-nuts, or any other crop that he may grow between the trees. The most lucrative product in East Africa is *tembo*, a liquor obtained from the cut end of the very young flowering spike. The Department of Forestry in the same colony has also inaugurated a series of leaflets, the first of which deals with timber trees, including a juniper, a Podocarpus, *Pygeum africanum*, and *Allophylus abyssinicus*.

WE have received a pamphlet entitled "The Growth of Oak in High Forest," by Prof. W. R. Fisher, president of the Royal English Arboricultural Society, in which the author points out the desirability of having a model oak high forest as an adjunct to the forestry school at Oxford. In spite of the fact that oak forests and oak timber have played such an important part in the history of England, we have not at the present day a typical example of oak high wood, that is, an area where all stages from the seedling to the mature tree are represented. In the above pamphlet Prof. Fisher proposes to have a working section of the oak wood in Windsor Park set aside for this purpose. The area required, 1200 acres, could surely be spared for this important purpose, and the author clearly shows how the present crop could with time be replaced by a series of age classes representing all stages in the growth of the tree and the forest from the beginning to the end of the rotation. The financial returns would be vastly increased thereby, more than counterbalancing and justifying any small initial sacrifice. The scheme deserves every encouragement, and we trust will be looked upon with favour by those in authority.

ONE of the best concise accounts of the Liége International Exhibition yet published is contributed by Mr. L. Ramakers to the October issue of the *Engineering Magazine*. Some excellent illustrations are given of the mechanical, mining, and metallurgical features. Several large engines for operation with blast-furnace waste gas were shown, notably a 1200 horse-power four-cycle double-acting horizontal tandem engine for the direct driving of a rolling mill at the Cockerill works. Another gas engine shown by the same firm is a 500 horse-power four-cycle double-acting twin cylinder for operation with coke-oven waste gas. A gas-producer of novel type was exhibited by the Deutz Gas Engine Works, the fuel for which consists of brown-coal briquettes. The same firm showed an eight horse-power locomotive with a benzene motor.

FROM the Rationalist Press Association there come cheap reprints of "The Fundamental Principles of the Positive Philosophy" and of Haeckel's "The Wonders of Life." The former book contains a translation of the two introductory chapters of Comte's "Philosophie Positive," that is, the account of Comte's main theses, of the law of the three states of knowledge and the nature of positive philosophy, together with the fulminations against introspective psychology which are now completely out of date. Haeckel's work is a supplement to the "Riddle of the Universe," and discusses life, death, morality, and many other things.

OUR ASTRONOMICAL COLUMN.

THE RECENT LARGE SUN-SPOT.—The accompanying reproduction shows the form and extent of the large sun-spot group referred to in these columns last week. This photograph was taken at 12 o'clock noon on Thursday last, October 19, when the group was plainly visible to the naked eye. A rough measurement shows that the group was then more than 100,000 miles long and about 55,000 miles across its greatest breadth. The smaller spot, seen in the N.W. quadrant, was of particular beauty, showing a very dark circular umbra surrounded by a symmetrical penumbra.

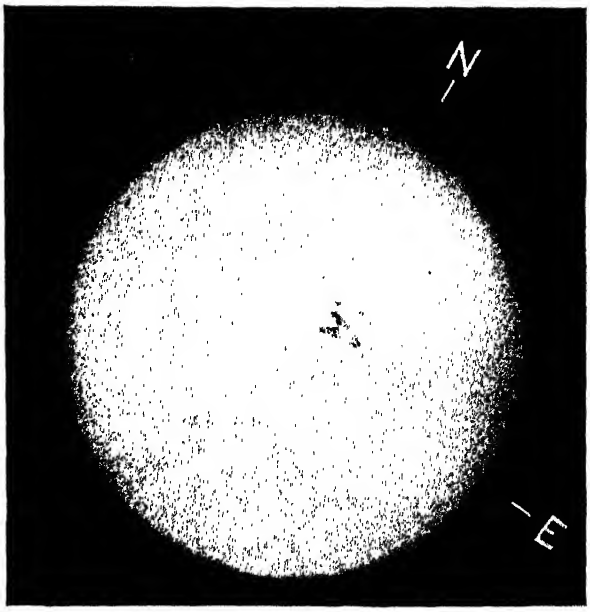


FIG. 1.—Photograph of the Sun showing the large group of sun-spots October 19, 12 o'clock noon.

A second "naked-eye" spot having a large black nucleus was seen near to the eastern limb of the sun on Monday last. This is the second occasion during the present year that the sun has presented the unusual phenomenon of two naked-eye spots visible on the disc at the same time.

FURTHER RESULTS OF THE FRENCH ECLIPSE EXPEDITIONS.—Yet another batch of the preliminary results obtained by French expeditions during the recent total eclipse of the sun is published in No. 15 of the *Comptes rendus*.

Prof. Janssen, who was in charge of the expedition stationed at Alcosebre (Spain), describes the observations which were made and the instruments which were employed at that station, and separate reports are pre-

sented by M.M. M. Stefanik, G. Millochau, and J. J. Landerer, who were in charge of the several instruments.

The results, which are of only a preliminary nature, are too numerous to give in detail here, but all the observations, both visual and photographic, appear to have been successful.

M. E. Stephan, of the Marseilles Observatory, was placed in charge of one of the expeditions organised by the Bureau des Longitudes, and, accompanied by M. Borrelly, occupied the same station as Mr. Newall, at Guelma (Algeria).

The equipment of this expedition consisted of a telescope of 40 cm. aperture and an equatorial of 9·5 cm. aperture and 190 cm. focal length. A number of visual observations of the corona, the prominences, &c., were successfully made.

NOVA AQUILÆ No. 2.—Circular No. 106 of the Harvard College Observatory describes the discovery and subsequent observations of Nova Aquilæ No. 2. The Nova was discovered on a plate taken with the 11-inch Draper telescope on August 18 for the Henry Draper memorial series. The spectrum, although faint, showed the lines $H\delta$, $H\gamma$, 4272, 4646, and $H\beta$ very broad and bright, $H\gamma$ and $H\beta$ having accompanying dark lines on their more refrangible edges. The helium line 4640 is slightly stronger than 4272, and the whole spectrum closely resembles that of Nova Persei No. 2, as photographed on March 30, 1901.

Some two or three hundred plates of this region are included in the Harvard series, and twenty-nine of them, taken before August 18, have been examined, but no trace of the Nova before that date has been discovered.

Two photographs showing the region half a degree square around the Nova, taken on August 15, 1903, and August 31, 1905, respectively, are reproduced in the Circular, and on comparing them it is at once seen that the Nova does not appear on the former, although it is quite a conspicuous object on the latter plate; stars of magnitude 15·7 are shown on the earlier plate.

Prof. Pickering's tabulated statement of the observed magnitudes of the Nova from August 31 to September 22 shows that this object gradually decreased in brightness from magnitude 10·41 on the first named date to magnitude 11·23 on the second. When first photographed the Nova's magnitude was about 7·0.

It follows from the Harvard observations that the Nova first appeared between August 10 and August 18, but it is hoped that, when the plates taken at Arequipa during that period arrive at Cambridge (Mass.), this interval may be greatly reduced.

STAR WITH A LARGE PROPER MOTION.—The method employed at Harvard College Observatory for the detection of variable stars, viz. the superposition of a photographic plate upon a glass positive of the same region, photographed on an earlier date, has led to the discovery that the star A.G.C. 6886 has a large proper motion. Whilst thus examining two plates of the Large Magellanic Cloud, taken on April 11, 1898, and December 5, 1904, respectively, Miss Leavitt found that this star had moved appreciably during the interval, and a comparison of the positions given in several of the older catalogues compiled since 1825 confirmed the fact.

The discussion of the data obtained from the comparison showed that the annual proper motion in R.A. is $-0{\cdot}066$s., in declination $+1''.14$, and along a great circle $1''{\cdot}28$.

The total number of stars shown on the original negatives is about 300,000, and it is probable that none of these, except A.G.C. 6886, has an annual proper motion exceeding three-quarters of a second (Harvard College Observatory Circular, No. 105).

OBSERVATIONS OF PERSEIDS, AUGUST.—The detailed results of the Perseid observations, made at the meteorological observatory at Pavia on August 8, 9, 10, and 11, are given in No. 8, vol. xxxiv., of the *Memorie della Società degli Spettroscopisti Italiani*.

On the night of August 8–9 seven observers recorded 153 meteors, and determined the trajectories of 23 of them. The maximum horary rate occurred between 0h. and 1h. (August 9), during which time 53 meteors were seen. On the succeeding night the watch lasted from 22h. to 3h. 7m., and the same number of observers saw 252 meteors, of which they recorded the paths of 28. The maximum rate occurred during the last hour, when 93 meteors were seen. The third night produced 264 meteors, and of these the seven observers recorded the trajectories of 18 during their watch of 4h. 56m. The maximum horary rate of the whole shower, as observed at Pavia, was recorded during this watch, when 100 meteors were seen between 2h. and 3h. on the morning of August 11.

Of the 669 meteors seen during the three nights, 27 were recorded as being brighter than, and 139 as being equal to, the first magnitude, whilst "swift" and "white" were the descriptive terms applied to the majority of them.

MATHEMATICAL AND PHYSICAL SCIENCE AT THE BRITISH ASSOCIATION.

THE great number of astronomers present during the South African meeting caused astronomy to play a larger part in the proceedings of the section than it has done in recent years, and many of the most important communications and discussions were on astronomical subjects. The number of papers on pure mathematics and on physics was relatively small.

Of the mathematical papers, one by Prof. Harzer on ancient Japanese mathematics was of special interest. Prof. Harzer finds on examining ancient Japanese records and works that several of the theorems discovered in Europe during the seventeenth century were known at least as early to Japanese mathematicians. As an example, the expansion

$$(\text{arc}\sin y)^2 = \sum_0^\infty \frac{1}{\beta+1} \cdot \frac{2.4.6\ldots 2\beta}{1.3.5\ldots(2\beta+1)} y^{2\beta+2}$$

due to Kowa Seki (1642–1708) may be quoted.

Mr. M. Cashmore showed how chess magic squares, *i.e.* squares of numbers which add up to the same amount along every path across the square in the direction of a rook's, a bishop's, or a knight's move, can be constructed by superposing on each other two types of subsidiary squares, which can be formed by simple rules.

Prof. Perry gave an account of the approximate method he had used to determine the stresses which occur in a winding rope carrying a cage when the upper end of the rope is suddenly stopped.

Mr. H. G. Fourcade described his instrument for stereoscopic surveying. It consists of a photographic camera which may be fixed in turn at the two ends of a base line with its axis perpendicular to that line. In front of, and close to, the sensitive plate a *réseau* scale on a glass plate is placed, and is reproduced on the two photographs taken.

The two are examined together in a measuring machine similar to that used in stellar photography, and by means of micrometer screws any portion of the picture may be made to appear in relief and coincident with an index. The distance of that portion from the base line may then be determined from the micrometer readings. Each determination takes about two minutes, and with a base of 300 metres the probable error does not exceed 1 part in 1000 for a distance of 10,000 metres, and is less for shorter distances.

Prof. Perry raised the question of the teaching of elementary mechanics, and pointed out that the average boy who enters a technical college is so badly educated that his first year has to be "wasted in the study of school subjects." Then three years are found to be insufficient to teach him "everything an engineer is likely to want in his profession," which many colleges foolishly attempt to do, and a fourth or even a fifth year is added. He urged that in teaching science to boys from nine to thirteen the methods of Mr. Barlow, of "Sandford and Merton" fame, should be followed, until they know something of levers, weighing and measuring, specific gravities, barometers and thermometers, and of electricity and magnetism. At the age of fourteen a boy should know elementary algebra and trigonometry, should be able to differentiate and integrate, and apply the calculus. The principles that if forces are in equilibrium their vector sum is zero, and the sum of their moments about any axis is

zero, should be presented to him from many points of view. Force should be taken as the rate of change of momentum. All these facts should be brought out and illustrated by experiment, and it should be the object of the teacher to turn out a pupil with a thorough grasp of mechanical principles, and not one crammed with formulæ which he soon forgets.

With the report of the Mathematical Association committee on the teaching of mechanics Prof. Perry is substantially in accord, although he differs from it in wishing to retain the term "centrifugal force" and to abolish the "poundal."

Lord Kelvin communicated a paper on the kinetic and statistical equilibrium of ether in ponderable matter at any temperature. If two small spheres, one covered with black, the other with white cloth, were placed in space at the earth's distance from the sun, the temperature of the black sphere would be greater than that of the white. If the spheres were at a distance from the sun 1000 times as great, and 999 other suns were scattered through space, all at about that distance from the spheres, the difference of temperature would be one-thousandth of the former difference. Dr. Chree has found, using thermometers, that in bright sunlight the difference of temperature is 1° C. to 3° C. On a starlight night we might therefore expect a difference of 0·001° C. or 0·003° C.

Dr. J. T. Bottomley described his experiments on the cooling of a lamp-blacked or silvered copper sphere in an evacuated spherical copper enclosure kept first at the temperature of liquid air, then, when the sphere has cooled, raised to the temperature of boiling water. Temperatures were observed thermoelectrically. The present results agree with those found previously by Dr. Bottomley, and do not support Stefan's law.

The writer reviewed the recent experimental work on the thermal conductivities of substances, and pointed out that the balance of evidence is in favour of many substances decreasing in thermal conductivity as their temperature is raised.

Mr. A. Word gave a *résumé* of the work done during the past year in the Cavendish Laboratory and elsewhere which justifies the conclusion that all substances are more or less radio-active.

Prof. Beattie described his observations on atmospheric electricity in South Africa, and his attempt to connect the observed conductivity of the air with other meteorological phenomena, an attempt which he considered had proved unsuccessful.

Communications on the meteorology of South Africa by Dr. Mill and by Mr. R. F. Rendall were read, and Prof. Beattie gave an account of the present state of the magnetic survey of the country, and exhibited charts embodying the results for the declination. Necessarily the work has had to be confined to positions near the railways, and it will be necessary to provide some means of extending the field of operations, especially along the western coast of South Africa. The association made a grant of 100*l.* towards the expense of this extension.

Great interest was shown in Sir David Gill's account of the geodetic survey in South Africa and the African arc of meridian. After the completion of the survey of Cape Colony and Natal in 1892, it became necessary to determine with greater accuracy the position of the twentieth parallel of longitude north of the colony at points where it formed the boundary of British and German territory. The work was placed in Sir David Gill's hands by the two Governments, and completed in 1903. At the same time, under the auspices of the Rhodesian Government, surveys of northern and southern Rhodesia were being carried out, partly in connection with the Anglo-Portuguese boundary. Since the war, surveys of the Transvaal and Orange River Colony have made steady progress, and the results so far obtained were embodied in the chart of South Africa exhibited by Sir David Gill. Throughout the work the bases taken were measured with the help of wires which were compared with a standard base 400 feet long before and after use. The discordance in the measurements of the Gwibi base of about 70,000 feet amounted in the aggregate to 1 part in 1·5 millions, and this was the base measured with least accuracy.

As a result, it appears that along the meridian of 19° east longitude the curvature of the earth agrees with that given by Clarke's elements, but along meridian 26° east, and more markedly along meridian 30°, this appears not to be the case. A definite settlement of the question will only be possible after the connection of the Rhodesian triangulation with that of the rest of South Africa, a connection which will entail a cost of about 1600*l.* When this has been achieved, Sir David Gill will have made one step more towards the carrying out of his scheme for a great African arc of meridian extending from the Cape to Cairo, and by combination with the Russian-Scandinavian arc, a great arc from the Cape of Good Hope to the North Cape. The scheme has the hearty approval of Section A.

It is somewhat remarkable that at Cape Town the section should hear an account of a geodetic survey of a country within the Arctic circle, but the details of the geodetic survey of Spitsbergen given by its director, Dr. O. Backlund, proved of great interest. It was undertaken by the Swedish and Russian Governments, was carried out on the same lines as that in South Africa, and has given results of a high order of accuracy considering the difficulties of work in such a country. The values of *g* found at some of the stations in the mountainous parts of the country come out in defect by two or three figures in the fourth place.

One of the most important communications to the section was that of Prof. Kapteyn on star streaming. Prof. Kapteyn finds that the stars, the proper motions of which relative to the solar system have been determined, fall into two groups, one in which the motions take place in the main parallel to a line joining the sun to a point 7° south of α Orionis, the other with its motions parallel to the line joining the sun to a point 2° south of η Sagittarii. If the motions of these two streams be referred to the centre of gravity of the whole of the stars considered, their directions must be diametrically opposite. One of the vertices of these motions in opposite directions Kapteyn finds is close to ξ Orionis, and both lie in the central line of the Milky Way. Prof. Kapteyn does not hold that all motions must be in this line, but that there is a great preponderance of such motions, and that motions oblique to it get fewer the greater the obliquity. At this stage of the investigation he wishes to stand until further knowledge of the motions of stars in the line of sight has been obtained spectroscopically.

Dr. A. W. Roberts gave an account of the observations he has made during the past five years on the light fluctuations of certain southern binary stars, especially V. Puppis. He has succeeded in reaching a high degree of accuracy, and has determined the orbital elements of six stars by means of his observations, using the relations given by Rambaut. He finds the masses of two of the six systems to be 60 to 300 times, and the densities 0·00002 to 0·36 time, those of the sun. The large masses are somewhat exceptional, and Mr. Jeans suggested that the light curves of stars of pear shape would be found to agree with the observations made by Roberts. In support of this, Mr. Jeans gave an account of his investigation of the condensation of a gas occupying initially the whole of space about centres at distances apart approximately equal to that from the solar system to the nearer stars, and with the mass at each centre of the same order as that of the sun. Any one of these nuclei might take a spheroidal, ellipsoidal, or a pear shape, or separate into two parts, according to its velocity of revolution.

Mr. R. T. A. Innes gave an account of the state of double star astronomy in the southern hemisphere, and pointed out the importance of bringing up the observations in the southern to the same state as those in the northern hemisphere. He considers the position and climate of Johannesburg offer exceptional opportunities for the work, and suggested the provision of a telescope by the Transvaal Government. Sir David Gill supported this suggestion.

Of shorter communications it is only necessary to mention a few, *e.g.* Prof. E. W. Brown's on the present state of lunar theory and the necessity of a new set of lunar tables, and Dr. Rambaut's on a new instrument for measuring stellar photographs, to show that in interest and importance the sectional work in South Africa in no way falls behind that of the meetings at home.

C. H. Lees.

CHEMISTRY AT THE BRITISH ASSOCIATION.

THE papers contributed to Section B at the meetings in South Africa were naturally more limited in number and in range of subject than is usual at ordinary meetings of the association, the majority of the communications having reference either to the chemical aspects of agriculture or to subjects connected with the gold extracting industry. On the other hand, a very active part in the work of the section was taken by the South African chemists, and, almost without exception, the reading of a paper was followed by an animated and interesting discussion.

At Cape Town, the first day of meeting was set aside for the discussion of agricultural and biochemical questions. As it had been arranged that the presidential address should be delivered at Johannesburg, its place was taken by Mr. A. D. Hall's report on recent developments in agricultural science, in which many subjects of special interest in South Africa were discussed. Dealing with the fixation of atmospheric nitrogen through the agency of bacteria, the author pointed out that a sharp distinction must be drawn between the use of pure cultures on old cultivated lands and in new countries, where leguminous crops are often being grown for the first time, and that the behaviour of the lucerne plant under bacterial infection in South African soils is worthy of careful investigation in view of its economic importance in all semi-arid countries. He directed attention to the need of a systematic series of soil analyses, with the ultimate object of making soil maps that shall be of service to the agriculturist, and indicated how much still remains unknown regarding the nutrition of plants and how great is the importance of research in the particular functions of the various constituents of the crop, as it is only through such knowledge that the quality of crops may possibly be influenced in desired directions. A brief discussion of the subjects of acclimatisation and cross-breeding brought to a close an address which aroused very great interest. Dr. Horace T. Brown then gave an account of his researches on the assimilatory processes of plants, in the course of which he described his method by which the assimilative power of leaves was measured for the first time under natural conditions. The quantity of carbon dioxide abstracted from the air by leaves of measured area was estimated in a special absorption apparatus devised for the purpose, and thus it was possible to deduce the amount of carbohydrate formed. The total solar radiation falling on the leaf was measured, and the proportion of the radiant energy of sunlight absorbed and transmitted by the leaf was also arrived at. The author's investigations showed that the rate of growth is not entirely dependent upon the amount of sunshine, but also on secondary causes. The business was brought to a close by a short paper by Dr. E. F. Armstrong on the *rôle* of enzymes in plant economy, in which the author directed attention to the fundamental similarity between the action of acids and that of enzymes, the distinction between them arising from the fact that enzymes act selectively in consequence of their power of associating themselves with the hydrolyte. The condition of the carbohydrate in solution is of primary importance, but this condition may to some extent be determined by the enzyme.

At the second day's meeting, Prof. H. B. Dixon gave a historical sketch of researches made on the propagation of explosions in gases, and discussed Berthelot's theory and his own "sound wave" theory on the mode of propagation. With the aid of the lantern he showed how he had followed photographically the flame from its initiation until the setting up of the detonation, and demonstrated the influence of the position of the spark and of the length of the column of exploding gases. He also described experiments now in progress on the specific heats of gases at high temperatures, and explained how the velocity of sound in a heated gas may be determined. In a second paper Prof. Dixon described the method he has devised for determining the atomic weight of chlorine by the direct burning of a known weight of hydrogen in a known weight of chlorine, the hydrogen, prepared by the electrolysis of barium hydroxide, being occluded in palladium, and the chlorine, prepared by the electrolysis of fused silver chloride, being weighed in the liquid state. The atomic weight obtained is higher than that of Stas, but in close agreement with the recent results of Richards. Messrs. G. T. and H. W. Beilby gave an account of their experiments on the influence of phase changes on the tenacity of ductile metals at the ordinary temperature and at the boiling point of liquid air. They showed that when a wire of ductile metal is stretched to four or five times its original length by drawing it through the holes of a wire plate all the ordinary traces of crystalline structure disappear, but the wire still consists of minute granules of the crystalline phase embedded in a matrix of the amorphous phase. By lowering the temperature of drawing, the mixture approaches more nearly to the homogeneous amorphous state. Observations were made at 15° and at −180° on wires of copper, silver, and gold, which had been as completely as possible converted into the amorphous phase by wire drawing at the ordinary temperature, and in every case the tenacity observed was higher than any recorded by previous investigators for equally pure metals. The wires broken at the ordinary temperature showed no general stretching, but at the boiling point of liquid air all the wires stretched about 12 per cent. Dr. A. Midlay recorded his determinations of the viscosities of liquid mixtures at the temperature of their boiling points, which were made in the expectation that viscosity curves would be obtained similar in form to the boiling-point curves. In the case of benzene and methyl alcohol, the viscosities of which at the respective boiling points are nearly the same, the expectation appears to be realised, but where the viscosities of the pure liquids at their boiling points are not the same certain complications are met with.

The third day of meeting at Cape Town was set apart for communications from local chemists. Prof. P. D. Hahn gave an account of the remarkable thermal chalybeate spring at Caledon, in Cape Colony. With the aid of a tabular statement of the purity ratio of the most famous chalybeate springs, he showed that the Caledon water holds with the water of Spa the first place, but he pointed out that while the waters of most chalybeate springs are very low in temperature, the Caledon spring is unique in so far that the temperature of the water at the eye of the spring is 49° C. Mr. C. F. Juritz stated that for various reasons very scanty attention has hitherto been paid to purely scientific chemical research in Cape Colony, and gave an interesting account of several investigations made in the Government laboratory under his direction. A chemical survey of the soils of the colony (at present suspended for want of funds) has resulted in the examination of an area of 27,000 square miles, on an average one sample being taken for every 60 square miles. A number of the fodder plants of the Karroo have been examined as regards their nutritive value, estimations of tannin in the barks of various trees have been made, poisonous principles have been extracted from some indigenous plants, and an alkaloid resembling quinine therapeutically, but differing from it chemically, has been extracted from the umjela or quinine tree, which abounds in the Transkei. Clays have been found in various parts of the colony some of which compare favourably in chemical composition with the best fire clays, and mineral pitch has been observed in certain localities. Dr. H. Tietz, in a paper on the character of Cape wines, explained that at the Cape grapes always become perfectly ripe, and thus contain more sugar and less acid than the grapes of the wine-producing countries of Europe. Notwithstanding this, a standing reproach against Cape wines is based on the contention that they contain more acid than European wines. The author investigated this matter on some 300 samples of different Cape wines, and found that the allegation cannot be upheld.

At Johannesburg the proceedings of the section were inaugurated by the delivery of the address of the president, which was of quite exceptional interest. It was followed by a paper by Mr. H. F. Julian, in which an investigation of the part played by oxygen in the dissolution of gold by cyanide solutions was described. The author arrived at the conclusion that free oxygen plays no primary part in the reaction, any assistance given being of a secondary nature, and that, as a matter of fact, it exerts a retarding influence. According to his experiments, while the balance indicates that free oxygen is of material assist-

ance, the galvanometer points to its presence hindering the dissolution of the gold; the cause of the disagreement between the instruments he attributes to the formation of local voltaic circuits. Mr. H. A. White gave an account of a series of experiments which showed that thiocyanates in presence of such oxidising agents as ferric salts attack gold with considerable ease, and that thiosulphates exert a similar but less powerful influence. These salts are present in ordinary working cyanide solutions, and the presence of gold in mine reservoirs and in the soil under residue dumps is probably connected with their occurrence. Experiments adduced by the author indicate that in well exposed dumps thiocyanates alone are of significance in respect to the observed solution of gold. A process of residue treatment, based on these facts, is resulting in the profitable extraction of a large proportion of the gold in certain of the residue dumps on the Rand.

At the second day's meeting, Dr. J. Moir discussed the law governing the solubility of zinc hydroxide in alkalis, and as the result of a quantitative research stated the conclusion that the phenomenon is essentially an equilibrium between alkali and zincic acid, which may be reached from both sides, and which depends solely on the concentration of the free alkali. It was also shown that no definite chemical compounds exist in the solution. Mr. G. W. Williams read a paper on the functions of the metallurgical laboratory, dealing with the uses of the laboratory for the testing of supplies and for purposes of research, and with the *personnel* and equipment of a suitable laboratory. He emphasised the necessity for a highly trained staff, and pointed out defects in the training given in the great English universities. In a valuable contribution, Mr. S. H. Pearce stated and discussed various economic problems in metallurgy on the Rand. Each stage of the whole process of gold extraction was considered from the economic as well as from the scientific standpoint, and the results of the practical experience of years were summarised in a very clear and judicial manner. Much technical information, of value to all interested in gold extraction, was given in this paper. Mr. R. L. Cousens gave an account of the experiments which led him to conclude that a radio-active substance is present in a certain ore discovered in the Transvaal. If a further examination of the material confirms his belief that the radio-activity of the ore is due to the presence of radium, the result will be of interest in view of the fact that uranium is not present in the ore.

The third day of the meeting was devoted to agricultural chemistry. The proceedings were opened by Mr. A. D. Hall, who discussed in greater detail some of the problems touched on in his address at Cape Town. In a paper on Pretoria rain, Mr. H. Ingle stated that the rain falling at Pretoria for twelve months from February, 1904, was collected, and its content of nitrogen, existing as nitrates, nitrites, and ammonia, determined each week. The results showed that the quantity of combined nitrogen brought down in the rain at Pretoria is considerably greater than the average amounts in Europe, amounting in twelve months to 7·07 lb. of nitrogen per acre as compared with the average of 3·84 lb. per acre at Rothamsted. In a second paper Mr. Ingle communicated the results of the analyses of some eighty samples of soils collected in various parts of the Transvaal, and drew a comparison between European and Transvaal soils, with special reference to the interconnection of their chemical composition and fertility as indicated by field experience. He showed that to take English standards in judging of fertility from chemical analysis may lead to erroneous conclusions in the case of tropical or subtropical soils, and that if there be a sufficient supply of water a soil of apparently poor quality, from analytical results, may yield luxurious crops under the favouring conditions of growth existent in the Transvaal. Mr. E. H. Croghan, in a paper on the fuel of the midland districts of South Africa, pointed out that a large proportion of potash is found in the excreta of sheep fed in this dry and treeless region, resulting from the composition of the bushes, the foliage of which constitutes the chief food of sheep and cattle. Owing to want of water for irrigation the farmer does not use sheep excreta for manure, but for fuel, and the ashes frequently accumulate near the homestead. Attention was directed to the economic value of these ash heaps, either as a manure or as a source of potassium carbonate. Reports were presented by the committee on wave-length tables of the spectra of the elements, the committee on the study of hydro-aromatic substances, and the committtee on the transformation of aromatic nitroamines.

SCIENTIFIC RESEARCH IN MEDICINE.[1]

THAT great benefits to mankind have followed the discoveries of recent years is obvious to all, especially with regard to the causes and prevention of yellow fever and malaria. Research is a word heard on all sides; it is the enemy of authority, that tyrannous spirit which has hampered progress and retarded the advance of scientific medicine for centuries. Experimental medicine is responsible for the greatest advances which have been made in our knowledge of the cause, prevention, and cure of disease. Most important discoveries have exerted but a slight direct influence at their inception; their full significance has remained hidden for a time. The majority of such discoveries has been made by those engaged in research in the realms of pure science. Pure science is unselfish; its aim is not profit, yet it is the forerunner of that applied science which is more obtrusively the "servant of man." If we study disease, we must do so for the sake of knowledge, the scientific spirit must enter into our work. The "practical man" may not appreciate such ideals, but he is ever ready to use the discoveries of science for his own ends. All are not born with the instincts of research, but there are many in whom they lie dormant, and it should be the function of educational institutions to detect and foster such men and lead them on to do the work for which they are adapted. But too often from mere lack of means such men drift away into other fields of activity. To carry on research successfully a man needs an assured income. Is it possible that those who are able and willing to help human progress can continue to ignore the devotion and self-sacrifice of such men as Lazear, Myers, Dutton, Plehn, and others who have laid down their lives in the study of tropical medicine? Medical research needs endowment, and it is grievous to see that in this country, where so much is done for charity, so pitiably little is done for the advancement of learning. To teach science as it should be taught in properly equipped and organised institutions is far more expensive in the case of medicine than in that of any other professional school. It does not suffice to build laboratories; they must also be provided with sufficient funds and equipment to enable them to become working entities.

Those who have watched the progress of the London School of Tropical Medicine from its inception have witnessed a struggle upward which is worthy of all praise. This, and the sister institution in Liverpool, are known throughout the world for the excellent work accomplished by the members of the teaching staff and by some of the students they have sent forth. The London School has a great mission to fulfil; it has to train men in the methods they will be called on to employ in many parts of the world, and to give them the latest and the best to take with them on their distant journeys. It is to be hoped that the public will second the noble efforts that have been made to establish a centre for the study of the diseases which affect the inhabitants of the tropical countries of this vast Empire.

The Trend of Recent Investigation.

A survey of recent work in tropical medicine shows us that investigation is chiefly being directed to the study of protozoal diseases. No advances of fundamental importance have been made with regard to malaria since the classical investigations were published with which the names of Ross and Manson, Grassi, Bignami and Bastianelli will ever remain associated. The earlier work has been confirmed and extended by many investigators. The prevention of malaria by means of mosquito destruction and other measures directed against mosquitoes has been tried in various localities, in some instances with success,

[1] From an address delivered at the opening of the nineteenth session of the London School of Tropical Medicine on October 11, by Dr. George Nuttall, F.R.S.

in others with doubtful results. This is, however, only what might be expected in view of the diversified difficulties which must necessarily arise.

There has been a veritable flood of malaria literature of recent years, including an annual volume of "Atti della Società per gli studi della malaria," the series commencing in 1900, which has come to us from Italy. Mosquitoes have received an immense amount of attention, after being much neglected in the past. The number of genera and species and their classification have become subjects to bewilder all but specialists.

The important discoveries on sleeping sickness ushered in by the researches of Castellani, a pupil of this school, have been confirmed and extended by Bruce and his collaborators of the sleeping sickness commission. The relation of the flies belonging to the genus Glossina to the transmission of the trypanosomes is being actively studied, and many important questions we must hope are nearing their solution in connection with this most fatal malady. A contribution has just come to hand from Gray and Tulloch with regard to the multiplication of the parasites in Glossina, indicating that the belief recently expressed is warranted, namely, that the parasites undergo a cycle of development within the insects. Of importance in their bearing on the question of the development of trypanosomes in other than their vertebrate hosts are the investigations of Schaudinn on *Trypanosoma noctuae* in Culex, those of Brumpt on certain trypanosomes of fishes which undergo their cycle of development in leeches, and those of Prowazeck on the rat trypanosome, which he has demonstrated undergoes development in the rat louse (*Haematopinus spinulosus*).

Of recent discoveries, the one which to me appears to carry the greatest weight is that of Novy and McNeal. They have been the first to obtain pure cultures of Protozoa, maintaining trypanosomes of different species alive *in vitro* for many generations. There is no telling whither the methods they have given us may lead; they directly stimulated Leonard Rogers to experiments wherein he succeeded, by an ingenious method of his own, in cultivating another protozoon, the Leishmania, obtained from cases of kala-azar.

The work on the tick-transmitted diseases known as the piroplasmoses (redwater, &c.) occurring in cattle, sheep, horses, and dogs has been pursued in various parts of the world with great activity. The results appear to me to indicate, what I believe also holds for human malaria parasites, that we shall in time learn to distinguish different parasites which we at present consider to represent single species.

The investigations of Dutton and Todd on tick fever in the Congo Free State, announced in February, have gone to prove that this disease is transmitted by a tick (*Ornithodoros savignyi*) after it has infected itself with blood containing the Spirochætæ. This has been confirmed by Koch, if we may rely on what has appeared recently in German newspapers. It is, however, quite premature to assume that African tick fever and European relapsing fever are due to one and the same species of Spirochæta; in fact, it is highly probable that this is not the case, although the report in question refers to the Spirochætæ as one species. In relapsing fever in Europe the bedbug (Cimex) has long been suspected to be a carrier of the infective agent, a probability which was considerably heightened by Karlinski's observation of motile Spirochætæ in the bodies of the insects up to thirty days after they had fed on relapsing fever blood. Schaudinn, moreover, informs me that he has observed the multiplication of the *Spirochaeta obermeieri* in Cimex. These observations, following closely upon those published by Marchoux and Salimbeni, are of greatest interest and practical import. The last named authors demonstrated that a fatal disease of the fowl in Brazil is due to a Spirochæta which is transmitted through the agency of a tick (*Argas miniatus*), and this is capable of conveying the disease even six months after feeding on infected blood. These Spirochætæ multiply in the tick, and are present in large quantities in its body cavity throughout this period. These observations are very suggestive, since they demonstrate the long persistence of the parasites in their carriers, and render it probable that they will be found to be harboured much longer. Finally, the finding this year of *Spirochaeta pallida* in syphilis by Schaudinn and others in man, and by Metschnikoff and Roux in experimentally infected apes, cannot escape a passing notice.

It is of some interest to note that the close blood-relationship existing between the apes and man, demonstrated independently by means of the precipitins by Grünbaum and myself, served as a direct incentive for the experiments of Metschnikoff and Roux, Lassar, and Neisser, which proved that human syphilis is communicable to the chimpanzee and ourang outang.

Of interest has also been the further discovery this year of a number of new protozoal parasites in the blood of different animals, in addition to numerous new species of Trypanosoma. I refer to new forms called "Leucocytozoa" because they inhabit the white blood corpuscles of their vertebrate hosts. Leucocytozoa were first discovered by Bentley in dogs in India, and were described, without sufficient mention of this fact, by James. Another species has been found by A. Balfour in the rat (*M. decumanus*) in Khartoum; and lastly, W. S. Patton informs me that he has found a species in the squirrel (*Sciurus palmarum*) in India, and apparently observed developmental forms thereof in a louse. Balfour has, moreover, described a new Hæmogregarine occurring in the jerboa (*Jaculus jaculus*), and Graham-Smith in our laboratory has found another new endoglobular parasite in the mole. This by no means exhausts the "finds" of this year, but it will suffice to show that British workers are doing their share in furthering our knowledge in this regard.

Of the diseases due to Vermes I can say but little. The discovery of Catto's Schisostomum in this laboratory is familiar to you all. It is interesting to note, following on the experiments with *Ankylostoma duodenale* by Loos, proving that the embryo worm can infect by penetrating through the skin, that Boycott in London and Tenholt in Germany have confirmed the fact this year in two experiments conducted on medical men who volunteered for the purpose.

Again, it is apparent that the subject of immunity in relation to protozoal diseases is proving to be one of great difficulty, and the results hitherto obtained indicate that new methods will have to be devised if the problem is to be solved from a practical, and still more so from a scientific, standpoint. It is also obvious in this connection that the problems before us can only be solved by animal experiment, and this accentuates the need of our giving an increasing amount of attention to comparative pathology as we push on toward the alleviation of the ills to which our own flesh is heir.

Many matters have necessarily been left untouched, including even such important diseases as yellow fever and Malta fever, on which active work has been done. My object has been to seize upon a few salient facts with the view of showing how much has been accomplished within a short period, and how great are the opportunities of the workers in this school who are destined to labour in new fields in different parts of the world. Perhaps what I have said—in no spirit of presumption—will serve as an incentive to some of my hearers. Let me conclude with some wise words from the Talmud:—

> "The day is short and the work is great.
> It is not incumbent upon thee to complete
> the work, but thou must not therefore
> cease from it."

THE MECHANICS OF THE ASCENT OF SAP IN TREES.[1]

THE following remarks, relating to one of the most powerful and universal of the mechanical operations of organic nature, are based mainly on the numerous experimental results reported in Dr. A. J. Ewart's recent memoir.[2] Their chief object is to assert the view that we are not compelled to suppose the sap, in the column of vessels through which it rises, to be subject to the great actual pressure, amounting in high trees to many atmospheres, that is sometimes postulated. It is hardly

[1] By Prof. J. Larmor, Sec.R.S. Paper received at the Royal Society on June 29.

[2] *Roy. Soc. Proc.*, vol. lxxiv. p. 554; *Phil. Trans.*, B, vol. cxcviii. p. 41.

necessary to remark that the problem of the rise of sap is one of mechanics, in so far as concerns the mode of the flow and the propelling power.

Contrary to the view above referred to, it seems not unreasonable to consider that the weight of the sap in each vessel is sustained in the main by the walls and base of that vessel, instead of being transmitted through its osmotically porous base to the vessels beneath it, and thus accumulated as hydrostatic pressure.

We could in fact imagine, diagrammatically (as happens in ordinary osmotic arrangements), a vertical column of vessels, each provided, say, with a short vertical side-tube communicating with the open air, in which the pressure is adjusted from moment to moment, and yet such that the sap slowly travels by transpiration from each vessel to the one next above, through the porous partitions between them, provided there is an upward osmotic gradient, *i.e.* if the dissolved substances are maintained in greater concentration in the higher vessels.[1] This difference of density must be great enough, between adjacent vessels, to introduce osmotic pressure in excess of that required to balance the head of fluid in the length of the upper one, into which the water has to force its way. Thus, in comparing vessels at different levels, the sap must be more concentrated in the upper ones by amounts corresponding to osmotic pressure more than counteracting the total head due to difference of levels, in order that it may be able to rise. As osmotic pressure is comparable with gaseous pressure for the same density of the molecules of the dissolved substance, the concentration required on this view is considerable, though not very great.

Such a steady gradient of concentration could apparently, on the whole, become self-adjusting, through assistance from the vital stimuli of the plant, for concentration in the upper vessels is promoted by evaporation. Yet pressures in excess or defect of the normal atmospheric amount might at times accumulate locally, the latter giving rise to the bubbles observed in the vessels, through release of dissolved gases.

It may be that this assumes too much concentration of dissolved material in the sap, *as it exists inside the vessels of the stem,* to agree with fact. In that case the capillary suction exerted from the nearest leaf-surface might be brought into requisition, after the manner of Dixon and Joly, to assist in drawing off the excess of water from the vessels. The aim proposed in this note is not to explain how things happen, which is a matter for observation and experiment, but merely to support the position that nothing abnormal from the passive mechanical point of view need be involved in this or other vital phenomena.

As regards estimating the amount of flow, at first sight it may not appear obvious, *a priori,* that the transpiration through a porous partition or membrane, due to osmotic gradient, is equal or even comparable in amount to what would be produced, with pure water, by a hydrostatic pressure-head equal to the difference of the osmotic pressures on the two faces of the partition. But more exact consideration shows that, on the contrary, osmotic pressure is *defined* by this very equality;[2] it is that pressure-difference which would produce such an opposite percolation of water as would just balance the direct percolation due to the osmotic attraction of the salt-solution.

[1] Thus, in an ordinary osmotic experiment with a **U**-tube, the percolation of water through the plug gradually *produces* a difference of hydrostatic pressure on its two faces, which is *sustained* by the fixity of the plug itself, but would be at once neutralised if the plug were free to slide in the tube. This increase of volume of the salt-solution, by the percolation of pure water into it, is on the van 't Hoff analogy correlated with the free expansion of the molecules constituting a gas. It goes on with diminished speed under opposing pressure, until a definite neutralising pressure is reached, inaptly called the osmotic pressure of the molecules of the solute, which just stops it, while higher pressures would reverse it. The stoppage is due to the establishment of a balance between the amounts of water percolating one way under osmotic attraction, and the opposite way under hydrostatic pressure. The pressure established, *e.g.* in an organic cell immersed in salt-solution, is thus really the reaction which is set up against the osmotic process. That process itself is perhaps more directly and intelligibly described as the play of osmotic affinity or attraction, even though it must be counted as of the same nature as the affinity of a gas for a vacuum. *Cf. Proc. Camb. Phil. Soc.*, January, 1897, or Whetham's "Theory of Solution," p 109.

[2] See preceding footnote.

It would, however, appear that the great resistance to flow offered by what botanists call Jamin-tubes, *viz.* thin liquid columns containing and carrying along numerous broad air-bubbles, is conditioned mainly by the viscosity of the fluid, and involves only indirectly the surface-tension of the bubbles. In fact, the resistance to flow may be expected to remain much the same if each bubble were replaced by a flat solid disc, nearly but not quite fitting the tube. Its high value arises from the circumstance that the mass of liquid between two discs moves on nearly as a solid block when the flow is steady, so that the viscous sliding has to take place in a thin layer close to the wall of the tube, and is on that account the more intense, and the friction against the tube the greater. The increased curvature of the upper capillary meniscus of the bubble is thus merely a gauge of the greater intensity of the viscous resistance instead of its cause, and modification of the surface-tension cannot be involved as a propelling power. The experimental numbers given by Dr. Ewart show that, even where the vessels are largely occupied by bubbles, the greater part of the resistance to active transpiration still resides in the partitions between them.

If the osmotic gradient, assisted possibly by capillary pull at the leaf-orifices, is insufficient to direct a current of transpiration upward, *capillary* alterations inside the vessels, arising from vitally controlled emission and absorption of material from the walls, cannot be invoked to assist: rather it must be *osmotic* alterations from one vessel to the next, of, so to speak, a peristaltic character, that might thus come into play. But any such alteration (of either kind) will involve local supply of energy. Is there a sufficient fund of energy, latent in the stem, to provide permanently the motive power for the elevation of the sap? In what form could this energy get transported there? The energies of the plant-economy come from the sunlight absorbed by the leaves. The natural view would appear to be that the work required to lift the sap is exerted at the place where the energy is received, and that it operates through extrusion of water by evaporative processes working against the osmotic attraction of the dissolved salts; while the maintenance of equilibrium along the vessels of the balanced osmotic column, with its semi-permeable partitions, demands that an equal amount of water must rise spontaneously to take the place of what is thus removed.

The subject might, perhaps, be further elucidated by observation of the manner in which the flow is first established at the beginning of the season, or possibly by experiments on the rate at which water would be absorbed by a wounded stem high above the ground.

EXPERIMENTS WITH THE LANGLEY AËRODROME.[1]

THE experiments undertaken by the Smithsonian Institution upon an aërodrome, or flying machine, capable of carrying a man have been suspended from lack of funds to repair defects in the launching apparatus without the machine ever having been in the air at all. As these experiments have been popularly, and of late repeatedly, represented as having failed on the contrary, because the aërodrome could not sustain itself in the air, I have decided to give this brief though late account, which may be accepted as the first authoritative statement of them.

It will be remembered that in 1896 wholly successful flights of between one-half and one mile by large steam-driven models, unsupported except by the mechanical effects of steam engines, had been made by me. In all these the machine was first launched into the air from "ways," somewhat as a ship is launched into the water, the machine resting on a car that ran forward on these ways, which fell down at the extremity of the car's motion, releasing the aërodrome for its free flight.

In the early part of 1898 the Board of Ordnance and Fortification of the War Department allotted 50,000 dollars for the development, construction, and test of a large aëro-

[1] Abridged from a paper by Dr. S. P. Langley in the Smithsonian Report for 1904.

drome, half of which sum was to be available immediately and the remainder when required.

The flying weight of the machine complete, with that of the aëronaut, was 830 pounds; its sustaining surface, 1040 square feet. It therefore was provided with slightly greater sustaining surface and materially greater relative horse-power than the model subsequently described which flew successfully. The brake horse-power of the engine was 52; the engine itself, without cooling water, or fuel, weighed approximately 1 kilogram to the horse-power. The entire power plant, including cooling water, carburettor, battery, &c., weighed materially less than 5 pounds to the horse-power. Engines for the large machine and for a model of the large machine one-fourth of its linear dimensions were completed before the close of 1901, and they were immediately put in their respective frames, and tests of them and of their power-transmission appliances were begun.

A test of the quarter-size model in actual flight was made on August 8, 1903, when the machine worked most satisfactorily, the launching apparatus, as always heretofore, performing perfectly, while the model, being launched directly into the face of the wind, flew directly ahead on an even keel. The balancing proved to be perfect, and the power, supporting surface, guiding, and equilibrium-preserving effects of the rudder also. The weight of the model was 58 pounds, its sustaining surface 66 square feet, and the horse-power from $2\frac{1}{2}$ to 3. This was the

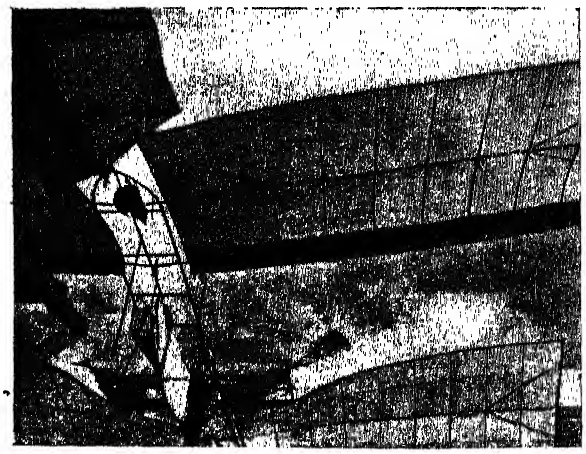

FIG. 1.—Reproduction of an instantaneous photograph, taken from the boat itself and hitherto unpublished, showing the aërodrome in motion before it had actually cleared the house boat. On the left is seen a portion of a beam, being a part of the falling ways in which the front wing was caught, while the front wing itself is seen twisted, showing that the accident was in progress before the aërodrome was free to fly.

first time in history, so far as I know, that a successful flight of a mechanically sustained flying machine was made in public.

Serious delays in the testing of the small machine were caused by changed atmospheric conditions, but they proved to be almost negligible compared with what was later experienced with the large one.

On October 7, 1903, the weather became sufficiently quiet for a test. In this, the first test, the engineer took his seat, the engine started with ease and was working without vibration at its full power of more than 50 horse, and the word being given to launch the machine, the car was released and the aërodrome sped along the track. Just as the machine left the track, those who were watching it, among whom were two representatives of the Board of Ordnance, noticed that the machine was jerked violently down at the front (being caught, as it subsequently appeared, by the falling ways) (Fig. 1), and under the full power of its engine was pulled into the water, carrying with it its engineer. When the aërodrome rose to the surface it was found that while the front sustaining surfaces had been broken by their impact with the water, yet the rear ones were comparatively uninjured. As soon as a full examination of the launching mechanism had been made it was found that the front portion of the machine had caught on the launching car, and that the guy post, to which were fastened the guy wires which are the main strength of the front surfaces, had been bent to a fatal extent. The machine, then, had never been free in the air, but had been pulled down as stated.

On December 8, 1903, a test was made at Arsenal Point, quite near Washington, though the site was unfavourable. The engine being started and working most satisfactorily, the order was given by the engineer to release the machine, but just as it was leaving the track another disaster, again due to the launching ways, occurred. This time the rear of the machine, in some way still unexplained, was caught by a portion of the launching car, which caused the rear sustaining surfaces to break, leaving the rear entirely without support, and it came down almost vertically into the water.

Entirely erroneous impressions have been given by the account of these experiments in the public Press, from which they have been judged, even by experts, the impression being that the machine could not sustain itself in flight. It seems proper, then, to emphasise and to reiterate, with the view of what has just been said, that the machine has never had a chance to fly at all, but that the failure occurred on its launching ways; and the question of its ability to fly is consequently, as yet, an untried one.

There have, then, been no failures so far as the actual test of the flying capacity of the machine is concerned, for it has never been free in the air at all. The failure of the financial means for continuing these expensive experiments has left the question of their result where it stood before they were undertaken, except that it has been demonstrated that engines can be built, as they have been, of little more than one-half the weight that was assigned as the possible minimum by the best builders of France and Germany; that the frame can be made strong enough to carry these engines, and that, so far as any possible prevision can extend, another flight would be successful if the launching were successful; for in this, and in this alone, so far as is known, all the trouble has come.

The experiments have also given necessary information about this launching. They have shown that the method which succeeded perfectly on a smaller scale is insufficient on a larger one, and they have indicated that it is desirable that the launching should take place nearer the surface of the water, either from a track upon the shore or from a house boat large enough to enable the apparatus to be launched at any time with the wings extended and perhaps with wings independent of support from guys. But the construction of this new launching apparatus would involve further considerable expenditures that there are no present means to meet; and this, and this alone, is the cause of their apparent failure.

Failure in the aërodrome itself or its engines there has been none; and it is believed that it is at the moment of success, and when the engineering problems have been solved, that a lack of means has prevented a continuance of the work.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The number of first-year students matriculated on Saturday, October 21, was 1008. Last year at the same date the number was 884. With those matriculated during the Lent and Easter terms, the total for the civil year 1905 is 1039; but this number will be slightly increased, as several freshmen were unable to attend on Saturday. Hitherto the largest entry has been 1027, in the year 1890. The number of medical students is 117; there is also a large entry of engineering students and of candidates for the economics tripos.

The professor of mineralogy has, with the consent of the Vice-Chancellor, re-appointed Mr. A. Hutchinson, of Pembroke College, to be demonstrator in mineralogy and assistant curator for five years from January 1, 1906.

The special board for biology and geology has nominated Mr. F. A. Potts, of Trinity Hall, to use the university table at Naples for six months as from October 1, 1905.

A university lectureship in mathematics is vacant by the resignation of Mr. Jeans, who has accepted a professorship at Princeton University, New Jersey. The general board of studies will shortly proceed to appoint a lecturer to hold office from Christmas, 1905, until Michaelmas, 1910. The annual stipend is 50*l*. The lecturer will be expected to lecture on applied mathematics. Candidates are requested to send in their applications, with statements of the branches of mathematics in which they are prepared to lecture, and with testimonials if they think fit, to the Vice-Chancellor on or before November 6.

Science announces that New York University has received 5000*l*. by the will of the late William A. Wheelock.

SOME excellent views of the plant and equipment of the workshops and laboratories at Birmingham University are given in illustration of a series of articles by Mr. C. Alfred Smith in *Engineering*.

DR. ALEXANDER MCKENZIE, lecturer and senior demonstrator in the University of Birmingham, has been appointed head of the chemical department at the Birkbeck College in succession to Dr. John E. Mackenzie, who has accepted the appointment of principal of the Technical Institute, Bombay.

THE Ontario Government has selected, says *Science*, the following men to compose a commission to report on the proposed reorganisation of the University of Toronto:—Prof. Goldwin Smith, Sir William Meredith, Messrs. A. H. N. Colquhoun, Byron E. Walker, J. W. Flavelle, the Rev. Canon Cody, and the Rev. D. B. Macdonald.

THE classes in craft instruction in photography and process work at the Regent Street Polytechnic were inaugurated by a social re-union on October 17. We notice the time-table for the present session includes classes in practical and technical photography, studio operating, retouching, finishing in colours, photo-engraving, and in colour photography.

THE Bishop of Birmingham, delivering the presidential address to the members of the Midland Institute at Birmingham on October 13, took for his subject "What is an Educated Man?" He said the uneducated man is without an ideal, consciously held and deliberately striven after. He may be a specialist of trained faculty, but, if he has no general ideal enabling him to give his special subject its place in human progress as a whole, he remains a trained specialist rather than an educated man. The educated man knows something of modern scientific method and achievement. Then the world becomes to him the scene of great constant forces which admit of being guided and directed and combined to promote the purpose of human progress. A man to become educated need not have time to read much, if he reads the right books. He ought to know some one other language than his own, and enlarge his study in some other literature. A man who has read carefully any one of the works of Darwin will know what real scientific caution is, coupled with the widest power of hypothesis.

A COPY of the annual report of the Glasgow and West of Scotland Technical College has been received. The total expenditure to date on the site, building, and equipment of the first section of the new building, the memorial stone of which was laid by the King two and a half years ago, has been 163,060*l*.; the building and equipment fund now stands at 209,763*l*., of which 198,845*l*. has been received. The small balance available after payment of the liabilities already incurred is not sufficient to enable the governors to proceed with the remaining section of the building, but it is hoped that they will soon be placed in a position to complete the scheme originally proposed. In addition to the subscriptions to the building and equipment fund, the college will receive a legacy of 20,000*l*. under the will of the late Mr. James Donald, and also the residue of his estate. This welcome addition to the resources of the college is to be used in the development of the facilities already existing for the study of chemistry and mechanics. The scheme for the coordination of certain of the continuation classes conducted by the school boards of Glasgow and Govan with the corresponding classes in the college was in force during last session, but did not work so satisfactorily as was anticipated. The necessity for a closer linking together of the two systems was felt, and an officer of the college has been appointed as superintendent of the continuation classes concerned, whose principal duty is to keep in close touch with the teachers, both of the college and the school boards, and whose active mediation will, it is hoped, secure the carrying out of the scheme of work agreed upon.

SOCIETIES AND ACADEMIES.

LONDON.

Entomological Society, October 5.—Mr. F. Merrifield, president, in the chair.—Mr. E. **Harris** showed living larvæ of *Cordylomera saturalis*, taken from a log of mahogany imported from the Sekondi district of the Gold Coast, together with the perfect beetle, which was dead at the time the discovery was made.—Mr. A. T. **Rose** exhibited a remarkable melanic specimen of *Catocala nupta*, taken by Mr. Lewis in his garden at Hornsey, N., in September. The coloration of the lower wings was of a dull brown, and all the markings of the upper wings were strongly intensified.—Mr. N. H. **Joy** brought for exhibition Coleoptera taken during a three days' trip to Lundy Island in August, including *Melanophthalma distinguenda*, Con., a species new to Britain; *Stenus ossium* var. *insularis*, a variety apparently new to science; and *Ceuthorrhynchus contractus* var. *pallipes*, Crotch, peculiar to the island. One hundred and sixty-three species were taken on the island, about eighty of which are not recorded in Wollaston's and F. Smith's lists of Lundy Coleoptera.—Mr. A. **Sich** showed examples of *Argyresthia illuminatella*, Z., two of the four specimens taken near Hailsham, Sussex, on June 15 this year. They were beaten off Pinus, and until examined with a lens were supposed to be *Ocnerostoma piniariella*, of which species two were also exhibited for comparison.—Mr. W. J. **Lucas** exhibited the larva, cocoon, and the subsequent imago of an "ant-lion," *Myrmeleo formicarius*, from two Spanish larvæ given him by Dr. T. A. Chapman last autumn. The difference in size between the small larva and the large perfect insect was remarkable. He also showed a living ♀ of the rather scarce grasshopper *Stenobothrus rufipes*, taken in the New Forest at the end of August, and kept alive by feeding on grass.—Mr. G. C. **Champion** exhibited several examples of *Lymexylon navale*, L., from the New Forest, where it was not often found.—Mr. A. H. **Jones** showed series of *Lycaena argus* (*aegon*, Schiff.), var. *hypochiona*, taken on the North Downs this year, approaching the form of *L. argyrognomon* taken not uncommonly in the Rhone Valley. Together with these he had arranged for comparison typical British *L. argus*, L., *L.* var. *corsica*, from Tattone, Corsica, and a series of *L. argyrognomon*, Brgstr. (*argus*, auctorum), from Chippis, near Sierre.—Colonel J. W. **Yerbury** exhibited specimens of *Hammerschmidtia ferruginea*, Fln., from Nethy Bridge, the first authentic British specimens; also *Microdon latifrons*, Lw., a specimen of which, taken at Nethy Bridge June 18, 1900, he had wrongly identified as *M. devius*, and under this name it was recorded in Verrall's "British Flies"; and of *Chamaesyrphus scaevoides*, Fln., a single specimen swept on June 15 in the Abernethy Forest near Forest Lodge.—Mr. H. J. **Turner** exhibited series of four species of the genus Coleophora, *C. alcyonipennella*, *C. lixella*, *C. albitarsella*, and *C. badiipennella*, together with the larval cases mounted *in situ* on the ruined leaves of their respective food plants. He also exhibited living larvæ and their cases, of *Goniodoma limoniella* on *Statice limonium*, *Coleophora obtusella* on *Juncus maritimus*, and *C. glaucicolella* (?) on *Juncus glaucus*, found in the Isle of Wight.—Commander J. J. **Walker** read a paper by Mr. A. M. Lea entitled "The Blind Coleoptera of Australia and Tasmania," and exhibited specimens of *Illaphanus stephensi*, Macl., from Watson's Bay, Sydney, N.S.W., and *Phycochus graniceps*, Broun, and *P. sulcipennis*, Lea, from Hobart, Tasmania.

MANCHESTER.

Literary and Philosophical Society, October 17.—Sir William H. Bailey, president, in the chair.—The "shadow bands" seen during the total eclipse observed at Burgos, in Old Castile, on August 30: T. **Thorp**.—Inaugural address: the **President** (see p. 637).

PARIS.

Academy of Sciences, October 16.—M. Troost in the chair.—On the absolute desiccation of vegetable products: L. **Maquenne**. It is commonly assumed that when a substance has been heated in an air oven at 100° C. to 120° C. until its weight becomes constant, all the moisture has been driven off. The author shows that this is not the case for substances such as starch and flour. For complete drying, either a current of well dried gas must be passed over the starch at about 120° C., or it must be sealed up in a vacuum with a dehydrating agent for a long period.—Presentation of the twelfth volume of the "Mémorial du Dépôt général de la Guerre": Bouquet **de la Grye**. This volume includes the measurements of the new meridian of France from the bases of Paris, Perpignan, and Cassel. Attention is directed to the accuracy of the results obtained.—Preliminary note on the observation of the total solar eclipse of August 30 made at Guelma: MM. **Bourget** and **Montangerand**. Fifteen photographs were obtained during totality, different coloured screens being interposed. The plates are all good, and show excellent images of the corona and protuberances.—Observations on the total eclipse of the sun of August 30: J. Comas **Solá**. The observations, which were made at Vinaroz, included three photographs of the corona and of the spectra of the chromosphere.—On functions having a finite number of branches: Georges **Rémoundos**.—On the calculation of an arch in masonry: M. **Auric**.—On a phenomenon of cooling observed in silver wires plunged into water and through which electric currents are passing: E. **Rogovsky**. It is shown that the resistance of the wire depends on the magnitude of the current passing through it, this effect being due to the fact that all parts of the wire are not, under these conditions, at the same temperature. It is necessary, to obtain exact values of the resistance of wires in a liquid at the temperature of this liquid, to extrapolate from a series of observations made with different intensities of current.—On the forms of lightning conductors: G. M. **Stanoïévitch**.—The basic character of pyranic oxygen. Halogen compounds of dinaphthopyryl with metals and metalloids: R. **Fosse** and L. **Lesage**. The radical dinaphthopyryl, $-CH\langle{}^{C_{10}H_6}_{C_{10}H_6}\rangle O$, although not containing nitrogen, forms a large number of double salts, examples of which with platinum, lead, iron, zinc, tin, bismuth, arsenic, and antimony are given in the present note.—On the development of amylase during the germination of seeds: Jean **Effront**. The sugar-forming and liquefying powers of malt do not develop at the same rate during germination, the former being the more rapid and reaching a maximum, whilst the latter steadily increases with the time of germination.—The measurement of the mechanical work obtainable from Limousin cattle: M. **Ringelmann**.—On a new flagellated parasite of *Bombyx mori* (*Herpetomonas bombycis*): C. **Levaditi**.

NEW SOUTH WALES.

Royal Society, September 6.—Mr. H. A. Lenehan, president, in the chair.—Reinforced concrete, paper iii.: Prof. W. H. **Warren**. The following matters were dealt with:—(*a*) The adhesion of cement mortar and concrete to steel. (*b*) The experimental determination of the neutral axis in a plain concrete, and also in a reinforced concrete beam, and the curves of strain for loads increasing from zero to the load producing fracture; the determination of the true form of the stress curve from the actual strain curve in a plain and in a reinforced concrete beam. (*c*) The safe working stresses and the fundamental equations recommended for the design of reinforced concrete structure.—The occurrence of inclusions of basic plutonic rocks in a dyke near Kiama: C. A. **Sussmilch**.

DIARY OF SOCIETIES.

FRIDAY, OCTOBER 27.

PHYSICAL SOCIETY, at 5.—The Theory of Phasemeters: Dr. W. E. Sumpner.—Apparatus designed for measuring the Coronal Radiation during an Eclipse: Prof. H. L. Callendar, F.R.S.

SATURDAY, OCTOBER 28.

THE ESSEX FIELD CLUB, at 6.30 (at the Essex Museum of Natural History, Stratford).—Straw-Plaiting; a Lost Essex Industry: J. Chalkley Gould.

TUESDAY, OCTOBER 31.

FARADAY SOCIETY, at 8.—*Discussion*.—Alternate Current Electrolysis: Prof. Ernest Wilson.—Alternate Current Electrolysis as shown by Oscillograph Records: W. R. Cooper.—Note on the Crystalline Structure of Electro-deposited Copper: Prof. A. K. Huntington.—Some Observations Respecting the Relation of Stability to Electrochemical Efficiency in Hypochlorite Production: W. Pollard Digby.

WEDNESDAY, NOVEMBER 1.

ENTOMOLOGICAL SOCIETY, at 8.

SOCIETY OF PUBLIC ANALYSTS, at 8.—(1) A Rapid Method for the Determination of Tin in Copper-Tin Alloy; (2) Water from the Simplon Tunnel: A. G. Levy.—Notes on (1) Dika Oil; (2) Surin Fat: J. Lewkowitsch.—The Determination of Oxygen in Copper: L. Archbutt.

THURSDAY, NOVEMBER 2.

CHEMICAL SOCIETY, at 8.30.—Solution and Pseudo-solution, part iv., Some of the Arsenious Properties of Arsenious Sulphide and Ferric Hydrate: E. Linder and H. Picton.—The Molecular Conductivity of Water: P. Blackman.—The Stereoisomerism of Substituted Ammonium Compounds: H. O. Jones.—The Influence of very Strong Electromagnetic Fields on the Spark Spectra of Ruthenium, Rhodium, and Palladium; J. E. Purvis.—Note on the Fluorides of Selenium and Tellurium: E. B. R. Prideaux.—The Constitution of Glutaconic Acid: J. F. Thorpe.—Some Alkyl Derivatives of Glutaconic Acid and of 2:6-Dioxypyridine: H. Baron and J. F. Thorpe.—Note on the Formation of β-Methylglutaconic Acid and of $\alpha\beta$-Dimethylglutaconic Acid: F. V. Darbishire and J. F. Thorpe.

LINNEAN SOCIETY, at 8.—Plant Ecology, interpreted by Direct Response to the Conditions of Life: Rev. G. Henslow.

RÖNTGEN SOCIETY, at 8.15.—The Ruhmkorff Coil: Prof. Wertheim-Salomonson.

CIVIL AND MECHANICAL ENGINEERS' SOCIETY, at 8.—Sea Defences: Baron H. T. H. Siccama.

CONTENTS.

PAGE

The Study of Fishes. By H. G. 625
The Far East 626
Absorption Spectra. By E. C. C. B. 627
Our Book Shelf:—
Yvert: "Identification por las Impresiones digito-palmares (La Dactiloscopia)."—E. H. J. S. . . . 628
"Science in South Africa: a Handbook and Review" 628
Thomas: "Stone Gardens" 629
Watson: "Oblique and Isometric Projection" . . . 629
Letters to the Editor:—
Eclipse Phenomena.—Sir Oliver Lodge, F.R.S. . 629
Geometry of Position.—Sir Oliver Lodge, F.R.S. 629
Eclipse Predictions.—Dr. A. M. W. Downing, F.R.S. 629
Chelifers and House-flies.—Prof. Sydney J. Hickson, F.R.S. 629
The Rudimentary Hind Limbs of the Boine Snakes.—Frank E. Beddard, F.R.S. 630
A Rare Game Bird.—Sir Herbert Maxwell, Bart., F.R.S. 630
On a New Species of Guenon from the Cameroons.—Dr. Henry O. Forbes 630
The Absorption Spectrum of Benzene in the Ultra-violet Region.—Dr. E. C. C. Baly; Prof. J. Norman Collie, F.R.S. 630
Action of Radium Salts on Gelatin.—W. A. Douglas Rudge 631
The Problem of "Shadow-bands."—Catharine O. Stevens 631
Rhymes on the Value of π.—π 631
Experiments on Variations of Lepidoptera by Environment. (*Illustrated.*) By F. Merrifield . . . 632
Chemistry in the Service of the State 634
On the Origin of Eoliths 635
Notes 636
Our Astronomical Column:—
The Recent Large Sun-spot. (*Illustrated.*) 639
Further Results of the French Eclipse Expeditions . 639
Nova Aquilæ No. 2 640
Star with a Large Proper Motion 640
Observations of Perseids, August 640
Mathematical and Physical Science at the British Association. By Dr. C. H. Lees 640
Chemistry at the British Association 642
Scientific Research in Medicine. By Dr. George Nuttall, F.R.S. 643
The Mechanics of the Ascent of Sap in Trees. By Prof. J. Larmor, F.R.S. 644
Experiments with the Langley Aërodrome. (*Illustrated.*) By Dr. S. P. Langley 645
University and Educational Intelligence 646
Societies and Academies 647
Diary of Societies 648
